Decision Trees: Some exercises
Exemplifying
how to compute information gains
and how to work with *decision stumps*

CMU, 2013 fall, W. Cohen E. Xing, Sample questions, pr. 4
Timmy wants to know how to do well for ML exam. He collects those old statistics and decides to use decision trees to get his model. He now gets 9 data points, and two features: “whether stay up late before exam” (S) and “whether attending all the classes” (A). We already know the statistics is as below:

\[
\begin{align*}
Set(\text{all}) &= [5+, 4-] \\
Set(S+) &= [3+, 2-], Set(S-) &= [2+, 2-] \\
Set(A+) &= [5+, 1-], Set(A-) &= [0+, 3-]
\end{align*}
\]

Suppose we are going to use the feature to gain most information at first split, which feature should we choose? How much is the information gain?

You may use the following approximations:

<table>
<thead>
<tr>
<th>( N )</th>
<th>3</th>
<th>5</th>
<th>7</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \log_2 N )</td>
<td>1.58</td>
<td>2.32</td>
<td>2.81</td>
</tr>
</tbody>
</table>
\[
H(\text{all}) \stackrel{\text{not.}}{=} H[5+, 4-] \stackrel{\text{not.}}{=} H \left(\frac{5}{9}\right) = H \left(\frac{4}{9}\right) \stackrel{\text{def.}}{=} \frac{5}{9} \log_2 \frac{9}{5} + \frac{4}{9} \log_2 \frac{9}{4} = \log_2 9 - \frac{5}{9} \log_2 5 - \frac{4}{9} \log_2 4 \\
= 2 \log_2 3 - \frac{5}{9} \log_2 5 - \frac{8}{9} = -\frac{8}{9} + 2 \log_2 3 - \frac{5}{9} \log_2 5 = 0.991076
\]

\[
H(\text{all}|S) \stackrel{\text{def.}}{=} \frac{5}{9} \cdot H[3+, 2-] + \frac{4}{9} \cdot H[2+, 2-] = \ldots \\
= \frac{5}{9} \cdot 0.970951 + \frac{4}{9} \cdot 1 = 0.983861
\]

\[
H(\text{all}|A) \stackrel{\text{def.}}{=} \frac{6}{9} \cdot H[5+, 1-] + \frac{3}{9} \cdot H[0+, 3-] = \ldots \\
= \frac{6}{9} \cdot 0.650022 + \frac{4}{9} \cdot 0 = 0.433348
\]

\[
IG(\text{all}, S) \stackrel{\text{def.}}{=} H(\text{all}) - H(\text{all}|S) = 0.007215 \\
IG(\text{all}, A) \stackrel{\text{def.}}{=} H(\text{all}) - H(\text{all}|A) = 0.557728
\]

\[
IG(\text{all}, S) < IG(\text{all}, A) \iff H(\text{all}|S) > H(\text{all}|A)
\]
Decision stumps;
entropy, mean conditional entropy, and information gain:
some very convenient formulas to be used
when working with pocket calculators

Sebastian Ciobanu, Liviu Ciortuz, 2017
Consider the decision stump given in the nearby image. The symbols $a, b, c, d, e$ and $f$ represent counts computed from a training dataset (not provided). As you see, the label (or, output variable), here denoted by $Y$, is binary, and so is the attribute (or, input variable) $A$. Obviously, $a = c + e$ and $b = d + f$.

a. Prove that the entropy of [the output variable] corresponding to the partition associated to the test node in this decision stump is

$$H[a+, b−] = \frac{1}{a+b} \log_2 \left( \frac{(a + b)^{a+b}}{a^ab^b} \right) \text{ if } a \neq 0 \text{ and } b \neq 0.$$ 

b. Derive a similar formula for the entropy, for the case when the output variable has three values, and the partition associated to the test node in the decision stump would be $[a+, b−, c^*]$. 

(Note that there is no link between the last $c$ and the $c$ count in the above decision stump.)
c. Assume that for the above given decision stump we would have [all counts] $c, d, e$ and $f$ different from 0. Prove that the mean conditional entropy corresponding to this decision stump is

$$H_{\text{node}|\text{attribute}} = \frac{1}{a+b} \log_2 \left( \frac{(c+d)^{c+d}}{cd} \cdot \frac{(e+f)^{e+f}}{ef} \right).$$

d. Now suppose that one of the counts $c, d, e$ and $f$ is 0; for example, let’s consider $c = 0$. Infer the formula for the mean conditional entropy in this case.

e. Prove the following formula for the information gain corresponding to the above given decision stump, assuming that all $a, b, c, d, e$ and $f$ are strictly positive:

$$IG_{\text{node};\text{attribute}} = \frac{1}{a+b} \log_2 \left( \frac{(a+b)^{a+b}}{a^ab^b} \cdot \frac{c^cd^d}{(c+d)^{c+d}} \cdot \frac{e^ef^f}{(e+f)^{e+f}} \right).$$
WARNING!

A serious problem when using the above formulas on a pocket calculator is the fact that the internal capacity of representation for intermediate results can be overflowed.

For example, a pocket calculator Sharp EL-531VH can represent the number $56^{56}$ but not $57^{57}$. Similarly, the calculator made available by the Linux Mint operating system [see the Accessories menu] can represent $179^{179}$ but not $180^{180}$.

In such overflow cases, you should use the basic / general formulas for entropies and the information gain, because they make a better use of the log function.
Answer

a.

\[ H[a+, b-] = -(\frac{a}{a + b} \cdot \log_2 a + \frac{b}{a + b} \cdot \log_2 b) \]

\[ = -\frac{1}{a + b}(a \cdot \log_2 a + b \cdot \log_2 b) = -\frac{1}{a + b}\left(\log_2 \left(\frac{a}{a + b}\right)^a + \log_2 \left(\frac{b}{a + b}\right)^b\right) \]

\[ = -\frac{1}{a + b}\left(\log_2 \left(\frac{a^a}{(a + b)^a}\right) + \log_2 \left(\frac{b^b}{(a + b)^b}\right)\right) = -\frac{1}{a + b} \cdot \log_2 \left(\frac{(a + b)^{a+b}}{a^a \cdot b^b}\right) \]

b.

\[ H[a+, b-, c\ast] = -(\frac{a}{a + b + c} \cdot \log_2 a + \frac{b}{a + b + c} \cdot \log_2 b + \frac{c}{a + b + c} \cdot \log_2 c) \]

\[ = -\frac{1}{a + b + c}\left(\log_2 \left(\frac{a}{a + b + c}\right)^a + \log_2 \left(\frac{b}{a + b + c}\right)^b + \log_2 \left(\frac{c}{a + b + c}\right)^c\right) \]

\[ = -\frac{1}{a + b + c}\left(\log_2 \left(\frac{a^a}{(a + b + c)^a}\right) + \log_2 \left(\frac{b^b}{(a + b + c)^b}\right) + \log_2 \left(\frac{c^c}{(a + b + c)^c}\right)\right) \]

\[ = -\frac{1}{a + b + c} \cdot \log_2 \left(\frac{a^a \cdot b^b \cdot c^c}{(a + b + c)^{a+b+c}}\right) = \frac{1}{a + b + c} \cdot \log_2 \left(\frac{(a + b + c)^{a+b+c}}{a^a \cdot b^b \cdot c^c}\right) \]
c. 

\[ H_{\text{nod|attribut}} \overset{\text{def.}}{=} \frac{c + d}{a + b} \cdot H[c+, d-] + \frac{e + f}{a + b} \cdot H[e+, f-] \]

\[ = \frac{c + d}{a + b} \cdot \frac{1}{e + d} \cdot \log_2 \frac{(c + d)^{c+d}}{c^c \cdot d^d} + \frac{e + f}{a + b} \cdot \frac{1}{e + f} \cdot \log_2 \frac{(e + f)^{e+f}}{e^e \cdot f^f} \]

\[ = \frac{1}{a + b} \cdot \log_2 \left( \frac{(c + d)^{c+d}}{c^c \cdot d^d} \cdot \frac{(e + f)^{e+f}}{e^e \cdot f^f} \right). \]

d. 

\[ H_{\text{nod|attribut}} = \frac{e + f}{a + b} \cdot H[e+, f-] \]

\[ = \frac{e + f}{a + b} \cdot \left( \frac{e}{e + f} \cdot \log_2 \frac{e + f}{e} + \frac{f}{e + f} \cdot \log_2 \frac{e + f}{f} \right) \]

\[ = \frac{e + f}{a + b} \cdot \frac{1}{e + f} \left( e \cdot \log_2 \frac{e + f}{e} + f \cdot \log_2 \frac{e + f}{f} \right) \]

\[ = \frac{1}{a + b} \cdot \log_2 \frac{(e + f)^{e+f}}{e^e \cdot f^f}. \]

e. 

\[ IG_{\text{nod|attribut}} = \frac{1}{a + b} \cdot \log_2 \frac{(a + b)^{a+b}}{a^a \cdot b^b} - \frac{1}{a + b} \cdot \log_2 \left( \frac{(c + d)^{c+d}}{c^c \cdot d^d} \cdot \frac{(e + f)^{e+f}}{e^e \cdot f^f} \right) \]

\[ = \frac{1}{a + b} \cdot \log_2 \left( \frac{(a + b)^{a+b}}{a^a \cdot b^b} \cdot \frac{c^c \cdot d^d}{(c + d)^{c+d}} \cdot \frac{e^e \cdot f^f}{(e + f)^{e+f}} \right). \]
Important REMARKS (in Romanian)

1. Întrucât majoritatea calculatoarelor de buzunar nu au funcția \( \log_2 \) ci funcțiile \( \ln \) și \( \log_2 \), în formulele prezentate sau deduse la punctele \( a - e \) ar fi de dorit să schimbăm baza logaritmului. Aceasta revine – pe lângă înlocuirea lui \( \log_2 \) cu \( \ln \) sau \( \log_2 \) – la înmulțirea membrului drept cu \( 1/\ln 2 \), respectiv \( 1/\log_2 2 \).

2. Întrucât, la aplicarea algoritmului ID3, pentru alegerea celui mai bun atribut de pus în nodul curent este suficient să calculăm entropiile condiționale medii, va fi suficient să comparăm produsele de forma

\[
\frac{(c + d)^{c+d}}{c^c d^d} \cdot \frac{(e + f)^{e+f}}{e^e f^f}
\]

pentru compașii de decizie considerați la nodul respectiv și să alegem minimul dintre aceste produse.
Exemplifying the application of the ID3 algorithm on a toy *mushrooms* dataset

CMU, 2002(?) spring, Andrew Moore, midterm example questions, pr. 2
You are stranded on a deserted island. Mushrooms of various types grow widely all over the island, but no other food is anywhere to be found. Some of the mushrooms have been determined as poisonous and others as not (determined by your former companions’ trial and error). You are the only one remaining on the island. You have the following data to consider:

<table>
<thead>
<tr>
<th>Example</th>
<th>NotHeavy</th>
<th>Smelly</th>
<th>Spotted</th>
<th>Smooth</th>
<th>Edible</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>B</td>
<td>1</td>
<td>0</td>
<td>1</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>C</td>
<td>0</td>
<td>1</td>
<td>0</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>D</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>E</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>F</td>
<td>1</td>
<td>0</td>
<td>1</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>G</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>H</td>
<td>0</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>U</td>
<td>0</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>?</td>
</tr>
<tr>
<td>V</td>
<td>1</td>
<td>1</td>
<td>0</td>
<td>1</td>
<td>?</td>
</tr>
<tr>
<td>W</td>
<td>1</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>?</td>
</tr>
</tbody>
</table>

You know whether or not mushrooms A through H are poisonous, but you do not know about U through W.
For the a–d questions, consider only mushrooms A through H.

a. What is the entropy of Edible?

b. Which attribute should you choose as the root of a decision tree?
   Hint: You can figure this out by looking at the data without explicitly computing the information gain of all four attributes.

c. What is the information gain of the attribute you chose in the previous question?

d. Build a ID3 decision tree to classify mushrooms as poisonous or not.

e. Classify mushrooms U, V and W using the decision tree as poisonous or not poisonous.

f. If the mushrooms A through H that you know are not poisonous suddenly became scarce, should you consider trying U, V and W? Which one(s) and why? Or if none of them, then why not?
a.

\[ H_{Edible} = H[3^+, 5^-] \overset{\text{def.}}{=} -\frac{3}{8} \cdot \log_2 \frac{3}{8} - \frac{5}{8} \cdot \log_2 \frac{5}{8} = \frac{3}{8} \cdot \log_2 \frac{8}{3} + \frac{5}{8} \cdot \log_2 \frac{8}{5} \]

\[ = \frac{3}{8} \cdot 3 - \frac{3}{8} \cdot \log_2 3 + \frac{5}{8} \cdot 3 - \frac{5}{8} \cdot \log_2 5 = 3 \cdot \frac{3}{8} \cdot \log_2 3 - \frac{5}{8} \cdot \log_2 5 \]

\[ \approx 0.9544 \]
b.

NotHeavy

[3+, 5−]

[1+, 2−]

[2+, 3−]

Smelly

[3+, 5−]

[2+, 3−]

[1+, 2−]

Spotted

[3+, 5−]

[2+, 3−]

[1+, 2−]

Smooth

[3+, 5−]

[2+, 2−]

[1+, 3−]
c.

\[ H_{0/\text{Smooth}} \overset{\text{def.}}{=} \frac{4}{8} H[2+, 2-] + \frac{4}{8} H[1+, 3-] = \frac{1}{2} \cdot 1 + \frac{1}{2} \left( \frac{1}{4} \log_2 \frac{4}{1} + \frac{3}{4} \log_2 \frac{4}{3} \right) \]

\[ = \frac{1}{2} + \frac{1}{2} \left( \frac{1}{4} \cdot 2 + \frac{3}{4} \cdot 2 - \frac{3}{4} \log_2 3 \right) = \frac{1}{2} + \frac{1}{2} \left( 2 - \frac{3}{4} \log_2 3 \right) \]

\[ = \frac{1}{2} + 1 - \frac{3}{8} \log_2 3 = \frac{3}{2} - \frac{3}{8} \log_2 3 \approx 0.9056 \]

\[ I G_{0/\text{Smooth}} \overset{\text{def.}}{=} H_{\text{Edible}} - H_{0/\text{Smooth}} \]

\[ = 0.9544 - 0.9056 = 0.0488 \]
d.

\[ H_{0/\text{NotHeavy}} \defeq \frac{3}{8} H[1+, 2-] + \frac{5}{8} H[2+, 3-] \]

\[ = \frac{3}{8} \left( \frac{1}{3} \log_2 \frac{3}{1} + \frac{2}{3} \log_2 \frac{3}{2} \right) + \frac{5}{8} \left( \frac{2}{5} \log_2 \frac{5}{2} + \frac{3}{5} \log_2 \frac{5}{3} \right) \]

\[ = \frac{3}{8} \left( \frac{1}{3} \log_2 3 + \frac{2}{3} \log_2 3 - \frac{2}{3} \cdot 1 \right) + \frac{5}{8} \left( \frac{2}{5} \log_2 5 - \frac{2}{5} \cdot 1 + \frac{3}{5} \log_2 5 - \frac{3}{5} \log_2 3 \right) \]

\[ = \frac{3}{8} \left( \log_2 3 - \frac{2}{3} \right) + \frac{5}{8} \left( \log_2 5 - \frac{3}{5} \log_2 3 - \frac{2}{5} \right) \]

\[ = \frac{3}{8} \log_2 3 - \frac{2}{8} + \frac{5}{8} \log_2 5 - \frac{3}{8} \log_2 3 - \frac{2}{8} \]

\[ = \frac{5}{8} \log_2 5 - \frac{4}{8} \approx 0.9512 \]

\[ \Rightarrow IG_{0/\text{NotHeavy}} \defeq H_{\text{Edible}} - H_{0/\text{NotHeavy}} = 0.9544 - 0.9512 = 0.0032, \]

\[ IG_{0/\text{NotHeavy}} = IG_{0/\text{Smelly}} = IG_{0/\text{Spotted}} = 0.0032 < IG_{0/\text{Smooth}} = 0.0488 \]
Important Remark (in Romanian)

În loc să fi calculat efectiv aceste câștiguri de informație, pentru a determina atributul cel mai „bun“, ar fi fost suficient să comparăm valorile entropiilor condiționale medii $H_{0/Smooth}$ și $H_{0/NotHeavy}$:

$$IG_{0/Smooth} > IG_{0/NotHeavy} \iff H_{0/Smooth} < H_{0/NotHeavy}$$

$$\iff \frac{3}{2} - \frac{3}{8} \log_2 3 < \frac{5}{8} \log_2 5 - \frac{1}{2} \iff 12 - 3 \log_2 3 < 5 \log_2 5 - 4$$

$$\iff 16 < 5 \log_2 5 + 3 \log_2 3 \iff 16 < 11.6096 + 4.7548 \text{ (adev.)}$$

În mod alternativ, ținând cont de formulele de la problema UAIC, 2017 fall, S. Ciobanu, L. Ciortuz, putem proceda chiar mai simplu relativ la calcule (nu doar aici, ori de câte ori nu avem de-a face cu un număr mare de instanțe):

$$H_{0/Netedă} < H_{0/Ușoară} \iff \frac{4^4}{2^2} \cdot \frac{4^4}{3^3} < \frac{5^5}{2^5} \cdot \frac{5^5}{2^5} \iff \frac{4^8}{3^3} < 5^5 \iff 4^8 < 3^3 \cdot 5^5 \iff 2^{16} < 3^3 \cdot 5^5$$

$$\iff 64 \cdot \frac{2^{10}}{1024} < 27 \cdot \frac{25 \cdot 125}{1000} > 3 \cdot \frac{8 \cdot 125}{1000} \text{ (adev.)}$$
Node 1: Smooth = 0
Node 2: Smooth = 1
The resulting ID3 Tree

IF (\textit{Smooth} = 0 AND \textit{Smelly} = 0) OR (\textit{Smooth} = 1 AND \textit{Smelly} = 1) THEN \textit{Edible};
ELSE \neg \textit{Edible};

Classification of test instances:

<table>
<thead>
<tr>
<th>U</th>
<th>Smooth = 1, Smelly = 1 ⇒ Edible = 1</th>
</tr>
</thead>
<tbody>
<tr>
<td>V</td>
<td>Smooth = 1, Smelly = 1 ⇒ Edible = 1</td>
</tr>
<tr>
<td>W</td>
<td>Smooth = 0, Smelly = 1 ⇒ Edible = 0</td>
</tr>
</tbody>
</table>
Exemplifying the *greedy* character of the ID3 algorithm

CMU, 2003 fall, T. Mitchell, A. Moore, midterm, pr. 9.a
Fie atributele binare de intrare $A, B, C$, atributul de ieșire $Y$ și următoarele exemple de antrenament:

<table>
<thead>
<tr>
<th>$A$</th>
<th>$B$</th>
<th>$C$</th>
<th>$Y$</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>0</td>
<td>0</td>
<td>1</td>
<td>0</td>
</tr>
</tbody>
</table>

a. Determinați arborele de decizie calculat de algoritmul ID3. Este acest arbore de decizie consistent cu datele de antrenament?
Răspuns

**Nodul 0**: (rădăcină)

Se observă imediat că primii doi “compaşi de decizie” (engl. decision stumps) au $IG = 0$, în timp ce al treilea compas de decizie are $IG > 0$. Prin urmare, în nodul 0 (rădăcină) vom pune atributul $C$. 
**Nodul 1**: Avem de clasificat instanțele cu $C = 1$, deci alegerea se face între atributele $A$ și $B$.

\[
\begin{array}{c}
\text{Nod 2} \\
\begin{array}{c}
[2+,1-] \\
0 \\
[1+,1-] \\
[1+,0-]
\end{array}
\end{array}
\begin{array}{c}
\text{A} \\
0 \\
1 \\
[1+,1-] \\
[1+,0-] \\
\end{array}
\begin{array}{c}
\text{B} \\
0 \\
1 \\
[1+,1-] \\
[1+,0-]
\end{array}
\]

Cele două entropii condiționale medii sunt egale:
\[
H_{1/A} = H_{1/B} = \frac{2}{3}H[1+,1-] + \frac{1}{3}H[1+,0-]
\]

Așadar, putem alege oricare dintre cele două atribute. Pentru fixare, îl alegem pe $A$. 
Nodul 2: La acest nod nu mai avem disponibil decât atributul $B$, deci îl vom pune pe acesta.

Arborele ID3 complet este reprezentat în figura alăturată.

Prin construcție, algoritmul ID3 este consistent cu datele de antrenament dacă acestea sunt consistente (i.e., necontradictorii). În cazul nostru, se verifică imediat că datele de antrenament sunt consistente.
b. Există un arbore de decizie de adâncime mai mică (decât cea a arborelui ID3) consistent cu datele de mai sus? Dacă da, ce concept (logic) reprezintă acest arbore?

Răspuns:
Din date se observă că atributul de ieşire $Y$ reprezintă de fapt funcţia logică $A \text{ XOR } B$.

Reprezentând această funcţie ca arbore de decizie, vom obţine arborele alăturat. Acest arbore are cu un nivel mai puţin decât arborele construit cu algoritmul ID3.

Prin urmare, arborele ID3 nu este optim din punctul de vedere al numărului de niveluri.
Aceasta este o consecință a caracterului “greedy” al algoritmului ID3, datorat faptului că la fiecare iterație alegem „cel mai bun“ atribut în raport cu criteriul câștigului de informație.
Se știe că algoritmii de tip “greedy” nu grantează obținerea optimului global.
Exemplifying the application of the ID3 algorithm in the presence of both categorical and continue attributes

CMU, 2012 fall, Eric Xing, Aarti Singh, HW1, pr. 1.1
As of September 2012, 800 extrasolar planets have been identified in our galaxy. Super-secret surveying spaceships sent to all these planets have established whether they are habitable for humans or not, but sending a spaceship to each planet is expensive. In this problem, you will come up with decision trees to predict if a planet is habitable based only on features observable using telescopes.

a. In nearby table you are given the data from all 800 planets surveyed so far. The features observed by telescope are Size (“Big” or “Small”), and Orbit (“Near” or “Far”). Each row indicates the values of the features and habitability, and how many times that set of values was observed. So, for example, there were 20 “Big” planets “Near” their star that were habitable.

<table>
<thead>
<tr>
<th>Size</th>
<th>Orbit</th>
<th>Habitable</th>
<th>Count</th>
</tr>
</thead>
<tbody>
<tr>
<td>Big</td>
<td>Near</td>
<td>Yes</td>
<td>20</td>

</tr>
</tbody>
</table>

Derive and draw the decision tree learned by ID3 on this data (use the maximum information gain criterion for splits, don’t do any pruning). Make sure to clearly mark at each node what attribute you are splitting on, and which value corresponds to which branch. By each leaf node of the tree, write in the number of habitable and inhabitable planets in the training data that belong to that node.
Answer: Level 1

\[ H(\text{Habitable}|\text{Size}) = \frac{35}{80} \cdot H\left(\frac{19}{35}\right) + \frac{45}{80} \cdot H\left(\frac{92}{225}\right) \]
\[ = \frac{35}{80} \cdot 0.9946 + \frac{45}{80} \cdot 0.9759 = 0.9841 \]
\[ IG(\text{Habitable}; \text{Size}) = 0.0128 \]

\[ H(\text{Habitable}|\text{Orbit}) = \frac{3}{8} \cdot H\left(\frac{47}{100}\right) + \frac{5}{8} \cdot H\left(\frac{43}{100}\right) \]
\[ = \frac{3}{8} \cdot 0.9974 + \frac{5}{8} \cdot 0.9858 = 0.9901 \]
\[ IG(\text{Habitable}; \text{Orbit}) = 0.0067 \]
The final decision tree

−  +  +  −
b. For just 9 of the planets, a third feature, Temperature (in Kelvin degrees), has been measured, as shown in the nearby table.

Redo all the steps from part a on this data using all three features. For the Temperature feature, in each iteration you must maximize over all possible binary thresholding splits (such as \( T \leq 250 \) vs. \( T > 250 \), for example).

<table>
<thead>
<tr>

According to your decision tree, would a planet with the features (Big, Near, 280) be predicted to be habitable or not habitable?

*Hint:* You might need to use the following values of the entropy function for a Bernoulli variable of parameter \( p \):

\[
H(1/3) = 0.9182, \ H(2/5) = 0.9709, \ H(92/225) = 0.9759, \ H(43/100) = 0.9858, \ H(16/35) = 0.9946, \ H(47/100) = 0.9974.
\]
Answer

Binary threshold splits for the continuous attribute Temperature:

![Graph showing binary threshold splits on a temperature axis with values at 205, 380, 260, 232.5, 320, 380.]
Answer: Level 1

\[ H(\text{Habitable}|\text{Size}) = 4 \cdot \frac{1}{9} + 5 \cdot H\left(\frac{2}{5}\right) = 4 \cdot \frac{1}{9} + 5 \cdot 0.9709 = 0.9838 \]

\[ H(\text{Habitable}|\text{Temp} \leq 232.5) = \frac{2}{3} \cdot H\left(\frac{1}{3}\right) = \frac{2}{3} \cdot 0.9182 = 0.6121 \]

\[ IG(\text{Habitable}; \text{Size}) = H\left(\frac{187}{400}\right) - 0.9838 \]
\[ = 0.9969 - 0.9838 = 0.0072 \]

\[ IG(\text{Habitable}; \text{Temp} \leq 232.5) = 0.3788 \]
Answer: Level 2

Note:
The plain lines indicate that both the specific conditional entropies and their coefficients (weights) in the average conditional entropies satisfy the indicated relationship. (For example, \( H(2/5) > H(1/3) \) and \( 5/6 > 3/6 \).)

The dotted lines indicate that only the specific conditional entropies satisfy the indicated relationship. (For example, \( H(2/2) = 1 > H(2/5) \) but \( 4/6 < 5/6 \).)
c. According to your decision tree, would a planet with the features (Big, Near, 280) be predicted to be habitable or not habitable?

Answer: habitable.

Assume that we learn a decision tree on this data. Assume that when the decision tree splits on the real-valued attribute \( X \), it puts the *split threshold* halfway between the attributes that surround the split. For example, using information gain as splitting criterion, the decision tree would initially choose to split at \( X = 5 \), which is halfway between \( X = 4 \) and \( X = 6 \) datapoints.

Let Algorithm DT2 be the method of learning a decision tree with only two leaf nodes (i.e., only one split).

Let Algorithm DT* be the method of learning a decision tree fully, with no pruning.

a. What will be the *training set error* for DT2 and respectively DT* on our data?

b. What will be the *leave-one-out cross-validation error* (LOOCV) for DT2 and respectively DT* on our data?

Applying ID3 on a dataset with two continuous attributes: decision zones

Liviu Ciortuz, 2017
Consider the training dataset in the nearby figure. $X_1$ and $X_2$ are considered countinous attributes.

Apply the ID3 algorithm on this dataset. Draw the resulting decision tree.

Make a graphical representation of the decision areas and decision boundaries determined by ID3.
Solution

Level 1:

- $H = 0$
- $H(1/3)$
- $X_1 < 9/2$
- $X_2 < 3/2$
- $X_2 < 5/2$

$\begin{align*}
H[Y|\cdot] &= 7/9 \times H(2/7) \\
H[Y|\cdot] &= 3/9 \times H(1/3) \\
H[Y|\cdot] &= 3/9 \times H(2/5) + 4/9 \times H(1/4) \\
H[Y|\cdot] &= 2/3 \times H(1/3)
\end{align*}$

$IG = 0.091$

$IG = 0.378$

$IG = 0.319$
Level 2:

\[ [4+,2-] \]
\[ X_1 < 5/2 \]
\[ [2+,0-] \quad [2+,2-] \]
\[ Y \quad N \]
\[ H=0 \quad H=1 \]
\[ IG=0.251 \]

\[ H[Y \mid .] = 2/3 \]

\[ [4+,2-] \]
\[ X_1 < 4 \]
\[ [2+,2-] \quad [2+,0-] \]
\[ Y \quad N \]
\[ H=1 \quad H=0 \]
\[ IG=0.251 \]

\[ [4+,2-] \]
\[ X_2 < 3/2 \]
\[ [1+,1-] \quad [3+,1-] \quad [3+,2-] \quad [1+,0-] \]
\[ Y \quad N \]
\[ H=1 \quad H(1/4) \quad H(2/5) \quad H=0 \]
\[ IG=0.04 \quad IG=0.251 \quad IG=0.109 \]

\[ H[Y \mid .] = 1/3 + 2/3 H(1/4) \quad H[Y \mid .] = 5/6 H(2/5) \]

Notes:

1. Split thresholds for continuous attributes must be recomputed at each new iteration, because they may change. (For instance, here above, 4 replaces 4.5 as a threshold for \( X_1 \).)
2. In the current stage, i.e., for the current node in the ID3 tree you may choose (as test) either \( X_1 < 5/2 \) or \( X_1 < 4 \).
3. Here above we have an example of reverse relationships between weighted and respectively un-weighted specific entropies: \( H[2+, 2-] > H[3+, 2-] \) but \( \frac{4}{6} \cdot H[2+, 2-] < \frac{5}{6} \cdot H[3+, 2-] \).
The final decision tree:

Decision areas:
Other criteria than IG for the best attribute selection in ID3:

Gini impurity / index and Misclassification impurity

CMU, 2003 fall, T. Mitchell, A. Moore, HW1, pr. 4
Entropy is a natural measure to quantify the impurity of a data set. The Decision Tree learning algorithm uses entropy as a splitting criterion by calculating the information gain to decide the next attribute to partition the current node.

However, there are other impurity measures that could be used as the splitting criteria too. Let’s investigate two of them.

Assume the current node $n$ has $k$ classes $c_1, c_2, \ldots, c_k$.

- **Gini Impurity**: $i(n) = 1 - \sum_{i=1}^{k} P^2(c_i)$.
- **Misclassification Impurity**: $i(n) = 1 - \max_{i=1}^{k} P(c_i)$.

a. Assume node $n$ has two classes, $c_1$ and $c_2$. Please draw a figure in which the three impurity measures (Entropy, Gini and Misclassification) are represented as the function of $P(c_1)$. 
Answer

Entropy \( p \) 

\[
Entropy(p) = -p \log_2 p - (1 - p) \log_2 (1 - p)
\]

Gini \( p \)

\[
Gini(p) = 1 - p^2 - (1 - p)^2 = 2p(1 - p)
\]

MisClassif \( p \)

\[
MisClassif(p) = \begin{cases} 
1 - (1 - p), & \text{for } p \in [0; 1/2) \\
1 - p, & \text{for } p \in [1/2; 1]
\end{cases}
\]

\[
= \begin{cases} 
p, & \text{for } p \in [0; 1/2) \\
1 - p, & \text{for } p \in [1/2; 1]
\end{cases}
\]
b. Now we can define new splitting criteria based on the Gini and Misclassification impurities, which is called Drop-of-Impurity in some literatures. That is the difference between the impurity of the current node and the weighted sum of the impurities of children.

For the binary category splits, Drop-of-Impurity is defined as

$$\Delta i(n) = i(n) - P(n_l)i(n_l) - P(n_r)i(n_r),$$

where $n_l$ and $n_r$ are the left and respectively the right child of node $n$ after splitting.

Please calculate the Drop-of-Impurity (using both Gini and Misclassification Impurity) for the following example data set in which $C$ is the class variable to be predicted.

<table>
<thead>
<tr>
<th>$A$</th>
<th>$a_1$</th>
<th>$a_1$</th>
<th>$a_1$</th>
<th>$a_2$</th>
<th>$a_2$</th>
<th>$a_2$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$C$</td>
<td>$c_1$</td>
<td>$c_1$</td>
<td>$c_2$</td>
<td>$c_2$</td>
<td>$c_2$</td>
<td>$c_2$</td>
</tr>
</tbody>
</table>
Gini: $p = 2/6 = 1/3 \Rightarrow$

\[
\begin{align*}
    i(0) &= 2 \cdot \frac{1}{3} \cdot \left(1 - \frac{1}{3}\right) = \frac{2}{3} \cdot \frac{2}{3} = \frac{4}{9} \\
    i(1) &= 2 \cdot \frac{2}{3} \cdot \left(1 - \frac{2}{3}\right) = \frac{4}{3} \cdot \frac{1}{3} = \frac{4}{9} \\
    i(2) &= 0
\end{align*}
\]

$\Rightarrow \Delta i(0) = \frac{4}{9} - \frac{3}{6} \cdot \frac{4}{9} = \frac{4}{9} - \frac{2}{9} = \frac{2}{9}$.

Misclassification: $p = 1/3 < 1/2 \Rightarrow$

\[
\begin{align*}
    i(0) &= p = \frac{1}{3} \\
    i(1) &= 1 - \frac{2}{3} = \frac{1}{3} \\
    i(2) &= 0
\end{align*}
\]

$\Rightarrow \Delta i(0) = \frac{1}{3} - \frac{1}{2} \cdot \frac{1}{3} = \frac{1}{6}$.  

c. We choose the attribute that can maximize the Drop-of-Impurity to split a node. Please create a data set and show that on this data set, Misclassification Impurity based $\Delta i(n)$ couldn’t determine which attribute should be used for splitting (e.g., $\Delta i(n) = 0$ for all the attributes), but Information Gain and Gini Impurity based $\Delta i(n)$ can.

**Answer**

<table>
<thead>
<tr>
<th>$A$</th>
<th>$a_1$</th>
<th>$a_1$</th>
<th>$a_1$</th>
<th>$a_2$</th>
<th>$a_2$</th>
<th>$a_2$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$C'$</td>
<td>$c_1$</td>
<td>$c_2$</td>
<td>$c_2$</td>
<td>$c_2$</td>
<td>$c_2$</td>
<td>$c_1$</td>
</tr>
</tbody>
</table>

**Entropy:** $\Delta i(0) = H[5+, 2-] - \left(\frac{3}{7}H[2+, 1-] + \frac{4}{7}H[3+, 1-]\right) = 0.006 \neq 0$;

**Gini:** $2 \left\{ \frac{2}{7} \left(1 - \frac{2}{7}\right) - \left[\frac{3}{7} \cdot \frac{1}{3} \left(1 - \frac{1}{3}\right) + \frac{4}{7} \cdot \frac{1}{4} \left(1 - \frac{1}{4}\right)\right]\right\} = 2 \left\{ \frac{10}{49} - \left[\frac{2}{21} + \frac{3}{28}\right]\right\}$

$= 2 \left(\frac{10}{49} - \frac{17}{84}\right) \neq 0$;

**Misclassification:** $\Delta i(0) = \frac{2}{7} - \left(\frac{3}{7} \cdot \frac{1}{3} + \frac{4}{7} \cdot \frac{1}{4}\right) = 0.$
Note: A [quite bad] property

If $C_1 < C_2$, $C_1^l < C_2^l$ and $C_1^r < C_2^r$ (with $C_1 = C_1^l + C_1^r$ and $C_2 = C_2^l + C_2^r$),
then the Drop-of-Impurity based on Misclassification is 0.

Proof

$$
\Delta i(n) = \frac{C_1}{C_1 + C_2} - \left( \frac{C_1^l + C_2^l}{C_1 + C_2} \cdot \frac{C_1^l}{C_1^l + C_2^l} + \frac{C_1^r + C_2^r}{C_1 + C_2} \cdot \frac{C_1^r}{C_1^r + C_2^r} \right)
$$

$$
= \frac{C_1}{C_1 + C_2} - \frac{C_1^l + C_1^r}{C_1 + C_2} = \frac{C_1}{C_1 + C_2} - \frac{C_1}{C_1 + C_2} = 0.
$$
Exemplifying pre- and post-pruning of decision trees using a threshold for the Information Gain

CMU, 2006 spring, Carlos Guestrin, midterm, pr. 4
[adapted by Liviu Ciortuz]
Starting from the data in the following table, the ID3 algorithm builds the decision tree shown nearby.

<table>
<thead>
<tr>
<th>V</th>
<th>W</th>
<th>X</th>

<td>0</td>
<td>0</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
</tbody>
</table>

a. One idea for pruning such a decision tree would be to start at the root, and prune splits for which the information gain (or some other criterion) is less than some small $\varepsilon$. This is called top-down pruning. What is the decision tree returned for $\varepsilon = 0.0001$? What is the training set error for this tree?
Answer

We will first augment the given decision tree with informations regarding the data partitions (i.e., the number of positive and, respectively, negative instances) which were assigned to each test node during the application of ID3 algorithm.

The information gain yielded by the attribute $X$ in the root node is:

$$H[3+;2−] - 1/5 \cdot 0 - 4/5 \cdot 1 = 0.971 - 0.8 = 0.171 > \varepsilon.$$ 

Therefore, this node will not be eliminated from the tree.

The information gain for the attribute $V$ (in the left-hand side child of the root node) is:

$$H[2+;2−] - 1/2 \cdot 1 - 1/2 \cdot 1 = 1 - 1 = 0 < \varepsilon.$$ 

So, the whole left subtree will be cut off and replaced by a decision node, as shown nearby. The training error produced by this tree is $2/5$. 

b. Another option would be to start at the leaves, and prune subtrees for which the information gain (or some other criterion) of a split is less than some small $\varepsilon$. In this method, no ancestors of children with high information gain will get pruned. This is called bottom-up pruning. What is the tree returned for $\varepsilon = 0.0001$? What is the training set error for this tree?

Answer:

The information gain of $V$ is $IG(Y; V) = 0$. A step later, the information gain of $W$ (for either one of the descendent nodes of $V$) is $IG(Y; W) = 1$. So bottom-up pruning won’t delete any nodes and the tree [given in the problem statement] remains unchanged. The training error is 0.
c. Discuss when you would want to choose bottom-up pruning over top-down pruning and vice versa.

Answer:

Top-down pruning is computationally cheaper. When building the tree we can determine when to stop (no need for real pruning). But as we saw top-down pruning prunes too much.

On the other hand, bottom-up pruning is more expensive since we have to first build a full tree — which can be exponentially large — and then apply pruning. The second problem with bottom-up pruning is that superfluous attributes may fullish it (see CMU, CMU, 2009 fall, Carlos Guestrin, HW1, pr. 2.4). The third problem with it is that in the lower levels of the tree the number of examples in the subtree gets smaller so information gain might be an inappropriate criterion for pruning, so one would usually use a statistical test instead.
Exemplifying
\(\chi^2\)-Based Pruning of Decision Trees
CMU, 2010 fall, Ziv Bar-Joseph, HW2, pr. 2.1
In class, we learned a decision tree pruning algorithm that iteratively visited subtrees and used a validation dataset to decide whether to remove the subtree. However, sometimes it is desirable to prune the tree after training on all of the available data.

One such approach is based on statistical hypothesis testing.

After learning the tree, we visit each internal node and test whether the attribute split at that node is actually uncorrelated with the class labels.

We hypothesize that the attribute is independent and then use Pearson’s chi-square test to generate a test statistic that may provide evidence that we should reject this “null” hypothesis. If we fail to reject the hypothesis, we prune the subtree at that node.
a. At each internal node we can create a **contingency table** for the training examples that pass through that node on their paths to the leaves. The table will have the $c$ class labels associated with the columns and the $r$ values the split attribute associated with the rows.

Each entry $O_{i,j}$ in the table is the number of times we observe a training sample with that attribute value and label, where $i$ is the row index that corresponds to an attribute value and $j$ is the column index that corresponds to a class label.

In order to calculate the chi-square test statistic, we need a similar **table of expected counts**. The expected count is the number of observations we would expect if the class and attribute are independent.

Derive a formula for each expected count $E_{i,j}$ in the table.

*Hint:* What is the probability that a training example that passes through the node has a particular label? Using this probability and the independence assumption, what can you say about how many examples with a specific attribute value are expected to also have the class label?
b. Given these two tables for the split, you can now calculate the chi-square test statistic

\[ \chi^2 = \sum_{i=1}^{r} \sum_{j=1}^{c} \frac{(O_{i,j} - E_{i,j})^2}{E_{i,j}} \]

with degrees of freedom \((r - 1)(c - 1)\).

You can plug the test statistic and degrees of freedom into a software package\(^a\) or an online calculator\(^b\) to calculate a \(p\)-value. Typically, if \(p < 0.05\) we reject the null hypothesis that the attribute and class are independent and say the split is statistically significant.

The decision tree given on the next slide was built from the data in the table nearby.

For each of the 3 internal nodes in the decision tree, show the \(p\)-value for the split and state whether it is statistically significant.

How many internal nodes will the tree have if we prune splits with \(p \geq 0.05\)?

\(^a\)Use 1-chi2cdf(x,df) in MATLAB or CHIDIST(x,df) in Excel.
\(^b\)(https://en.m.wikipedia.org/wiki/Chi-square_distribution#Table_of_IRQ872_value_vs_p-value.)

![Decision Tree Diagram]
Idea

While traversing the ID3 tree [usually in bottom-up manner], remove the nodes for which there is not enough (“significant”) statistical evidence that there is a dependence between the values of the input attribute tested in that node and the values of the output attribute (the labels), supported by the set of instances assigned to that node.

\hline
X_2 = 0 & 2 & 4 \\
& \frac{3}{3} & \frac{3}{3} \\
X_2 = 1 & 1 & 2 \\
& \frac{3}{3} & \frac{3}{3} \\
\hline
\end{array}
\]

\[
E_{X_4}(X_4 = 0, \text{Class } = 0) :
\]

\[
N = 12, \quad P(X_4 = 0) = \frac{1}{2} \quad \text{si} \quad P(\text{Class } = 0) = \frac{1}{3} \Rightarrow
\]

\[
N \cdot P(X_4 = 0, \text{Class } = 0) = N \cdot P(X_4 = 0) \cdot P(\text{Class } = 0) = 12 \cdot \frac{1}{2} \cdot \frac{1}{3} = 2
\]
\( \chi^2 \) Statistics

\[
\chi^2 = \sum_{i=1}^{r} \sum_{j=1}^{c} \frac{(O_{i,j} - E_{i,j})^2}{E_{i,j}}
\]

\[
\chi^2_{x_4} = \frac{(4 - 2)^2}{2} + \frac{(0 - 2)^2}{2} + \frac{(2 - 4)^2}{4} + \frac{(6 - 4)^2}{4} = 2 + 2 + 1 + 1 = 6
\]

\[
\chi^2_{x_1|x_4=0} = \frac{(3 - 2)^2}{2} + \frac{(1 - 2)^2}{2} + \frac{(0 - 1)^2}{1} + \frac{(2 - 1)^2}{1} = 3
\]

\[
\chi^2_{x_2|x_4=0,x_1=1} = \frac{\left(\frac{0 - 2}{3}\right)^2}{2} + \frac{\left(\frac{1 - 1}{3}\right)^2}{1} + \frac{\left(\frac{2 - 4}{3}\right)^2}{4} + \frac{\left(\frac{0 - 2}{3}\right)^2}{2} = \frac{4}{9} \cdot \frac{27}{4} = 3
\]

*p-values*: 0.0143, 0.0833, and respectively 0.0833.

The first one of these *p*-values is smaller than \( \varepsilon \), therefore the root node \( (X_4) \) cannot be prunned.

The AdaBoost algorithm:

*why* was it designed the way it was designed, and the convergence of the *training error*, in certain conditions

CMU, 2015 fall, Ziv Bar-Joseph, Eric Xing, HW4, pr. 2.1-5
CMU, 2009 fall, Carlos Guestrin, HW2, pr. 3.1
CMU, 2009 fall, Eric Xing, HW3, pr. 4.2.2
Consider $m$ training examples $S = \{(x_1, y_1), \ldots, (x_m, y_m)\}$, where $x \in \mathcal{X}$ and $y \in \{-1, 1\}$.
Suppose we have a weak learning algorithm $A$ which produces a hypothesis $h : \mathcal{X} \rightarrow \{-1, 1\}$ given any distribution $D$ of examples.

**AdaBoost** is an iterative algorithm which works as follows:

- Begin with a uniform distribution $D_1(i) = \frac{1}{m}$, $i = 1, \ldots, m$.
- At each iteration $t = 1, \ldots, T$,
  - run the weak learning algo. $A$ on the distribution $D_t$ and produce the hypothesis $h_t$;
  
  **Note (1):** Since $A$ is a weak learning algorithm, the produced hypothesis $h_t$ at round $t$ is only slightly better than random guessing, say, by a margin $\gamma_t$:
  \[
  \varepsilon_t = \text{err}_{D_t}(h_t) = \Pr_{x \sim D_t}[y \neq h_t(x)] = \frac{1}{2} - \gamma_t.
  \]

  **Note (2):** If at a certain iteration $t \leq T$ the weak classifier $A$ cannot produce a hypothesis better than random guessing (i.e., $\gamma_t = 0$) or it produces a hypothesis for which $\varepsilon_t = 0$, then the AdaBoost algorithm should be stopped.

- update the distribution
  \[
  D_{t+1}(i) = \frac{1}{Z_t} \cdot D_t(i) \cdot e^{-\alpha_t y_i h_t(x_i)} \quad \text{for} \quad i = 1, \ldots, m, \tag{2}
  \]
  where $\alpha_t = \frac{1}{2} \ln \frac{1 - \varepsilon_t}{\varepsilon_t}$, and $Z_t$ is the normalizer.

- In the end, deliver $H_T = \text{sign} \left( \sum_{t=1}^{T} \alpha_t h_t \right)$ as the learned hypothesis, which will act as a weighted majority vote.
We will prove that the training error $\text{err}_S(H_T)$ of AdaBoost decreases at a very fast rate, and in certain cases it converges to 0.

**Important Remark**

The above formulation of the AdaBoost algorithm states *no restriction* on the $h_t$ hypothesis delivered by the weak classifier $A$ at iteration $t$, except that $\varepsilon_t < 1/2$.

However, in another formulation of the AdaBoost algorithm (in a more general setup; see for instance MIT, 2006 fall, Tommi Jaakkola, HW4, problem 3), it is requested / recommended that hypothesis $h_t$ be chosen by (approximately) maximizing the [criterion of] *weighted training error* on a whole class of hypotheses like, for instance, decision trees of depth 1 (decision stumps).

In this problem we will not be concerned with such a request, but we will comply with it for instance in problem CMU, 2015 fall, Ziv Bar-Joseph, Eric Xing, HW4, pr2.6, when showing how AdaBoost works in practice.
a. Prove the following relationships:

i. \( Z_t = e^{-\alpha_t} \cdot (1 - \varepsilon_t) + e^{\alpha_t} \cdot \varepsilon_t \) (a consequence from (2))

ii. \( Z_t = 2\sqrt{\varepsilon_t(1 - \varepsilon_t)} \) (a consequence from i., and the value stated for \( \alpha_t \) in the AdaBoost pseudo-code)

iii. \( 0 < Z_t < 1 \) (a consequence derivable from ii.)

iv. \( D_{t+1}(i) = \begin{cases} \frac{D_t(i)}{2\varepsilon_t}, & i \in M^{\text{not.}} \{i | y_i \neq h_t(x_i)\}, \text{ i.e., the mistake set} \\ \frac{D_t(i)}{2(1 - \varepsilon_t)}, & i \in C^{\text{not.}} \{i | y_i = h_t(x_i)\}, \text{ i.e., the correct set} \end{cases} \) (a consequence derivable from (2) and ii.)

v. \( \varepsilon_i > \varepsilon_j \Rightarrow \alpha_i < \alpha_j \) (a consequence from the value stated for \( \alpha_t \) in the AdaBoost pseudo-code)

vi. \( \text{err}_{D_{t+1}}(h_t) = \frac{1}{Z_t} \cdot e^{\alpha_t} \cdot \varepsilon_t \), \text{ where err}_{D_{t+1}}(h_t) = \text{Pr}_{D_{t+1}}(\{x_i | h_t(x_i) \neq y_i\}) \)

vii. \( \text{err}_{D_{t+1}}(h_t) = 1/2 \) (a consequence derivable from ii. and v.)
Solution

a/i. Since $Z_t$ is the normalization factor for the distribution $D_{t+1}$, we can write:

$$Z_t = \sum_{i=1}^{m} D_t(i) e^{-\alpha_t y_i h_t(x_i)} = \sum_{i \in C} D_t(i) e^{-\alpha_t} + \sum_{i \in M} D_t(i) e^{\alpha_t} = (1 - \varepsilon_t) \cdot e^{-\alpha_t} + \varepsilon_t \cdot e^{\alpha_t}. \tag{3}$$

a/ii. Since $\alpha_t = \frac{1}{2} \ln \frac{1 - \varepsilon_t}{\varepsilon_t}$, it follows that

$$e^{\alpha_t} = \frac{1}{\varepsilon_t} \ln \frac{1 - \varepsilon_t}{\varepsilon_t} = e \ln \sqrt{\frac{1 - \varepsilon_t}{\varepsilon_t}} = \sqrt{\frac{1 - \varepsilon_t}{\varepsilon_t}} \tag{4}$$

and

$$e^{-\alpha_t} = \frac{1}{e^{\alpha_t}} = \sqrt{\frac{\varepsilon_t}{1 - \varepsilon_t}}. \tag{5}$$

So,

$$Z_t = (1 - \varepsilon_t) \cdot \sqrt{\frac{\varepsilon_t}{1 - \varepsilon_t}} + \varepsilon_t \cdot \sqrt{\frac{1 - \varepsilon_t}{\varepsilon_t}} = 2 \sqrt{\varepsilon_t(1 - \varepsilon_t)}. \tag{6}$$

Note that $\frac{1 - \varepsilon_t}{\varepsilon_t} > 1$ because $\varepsilon_t \in (0, 1/2)$; therefore $\alpha_t > 0$. 
a/iii.

The second order function $\varepsilon_t(1-\varepsilon_t)$ reaches its maximum value for $\varepsilon_t = 1/2$, and the maximum is $1/4$. Since $\varepsilon_t \in (0, 1/2)$, it follows from (6) that $Z_t > 0$ and $Z_t < 2\sqrt{1/4} = 1$.

a/iv. Based on (2), we can write:

$$D_{t+1}(i) = \frac{1}{Z_t} \cdot D_t(i) \cdot \begin{cases} e^{\alpha_t}, & \text{for } i \in M \\ e^{-\alpha_t}, & \text{for } i \in C. \end{cases}$$

Therefore,

$$i \in M \Rightarrow D_{t+1}(i) = \frac{1}{Z_t} \cdot D_t(i) \cdot e^{\alpha_t} = \frac{1}{2\varepsilon_t(1-\varepsilon_t)} \cdot D_t(i) \cdot \frac{\sqrt{1-\varepsilon_t}}{\sqrt{\varepsilon_t}} = \frac{D_t(i)}{2\varepsilon_t}$$

$$i \in C \Rightarrow D_{t+1}(i) = \frac{1}{Z_t} \cdot D_t(i) \cdot e^{-\alpha_t} = \frac{1}{2\varepsilon_t(1-\varepsilon_t)} \cdot D_t(i) \cdot \frac{\sqrt{\varepsilon_t}}{\sqrt{1-\varepsilon_t}} = \frac{D_t(i)}{2(1-\varepsilon_t)}.$$
a/v. Starting from the definition \( \alpha_t = \ln \sqrt{\frac{1 - \varepsilon_t}{\varepsilon_t}} \), we can write:

\[
\alpha_i < \alpha_j \iff \ln \sqrt{\frac{1 - \varepsilon_i}{\varepsilon_i}} < \ln \sqrt{\frac{1 - \varepsilon_j}{\varepsilon_j}}
\]

Further on, since both \( \ln \) and \( \sqrt{\cdot} \) functions are strictly increasing, it follows that

\[
\alpha_i < \alpha_j \iff \frac{1 - \varepsilon_i}{\varepsilon_i} < \frac{1 - \varepsilon_j}{\varepsilon_j} \iff \varepsilon_j (1 - \varepsilon_i) < \varepsilon_i (1 - \varepsilon_j) \iff \varepsilon_j - \varepsilon_i \varepsilon_j < \varepsilon_i - \varepsilon_i \varepsilon_j \iff \varepsilon_i > \varepsilon_j
\]

a/vi. It is easy to see that

\[
\text{err}_{D_{t+1}}(h_t) = \sum_{i=1}^{m} D_{t+1}(i) \cdot 1\{y_i \neq h_t(x_i)\} = \sum_{i \in M} D_t(i) e^\alpha_t = \frac{1}{Z_t} \sum_{i \in M} D_t(i) e^\alpha_t e^\alpha_t = \frac{1}{Z_t} \cdot \varepsilon_t \cdot e^\alpha_t
\]

(7)

a/vii. By substituting (6) and (4) into (7), we will get:

\[
\Rightarrow \text{err}_{D_{t+1}}(h_t) = \frac{1}{Z_t} \cdot \varepsilon_t \cdot e^\alpha_t = \frac{1}{2\sqrt{\varepsilon_t(1 - \varepsilon_t)}} \cdot \varepsilon_t \cdot \sqrt{\frac{1 - \varepsilon_t}{\varepsilon_t}} = \frac{1}{2}
\]
b. Show that $D_{T+1}(i) = \left( m \cdot \prod_{t=1}^{T} Z_t \right)^{-1} e^{-y_i f(x_i)}$, where $f(x) = \sum_{t=1}^{T} \alpha_t h_t(x)$.

c. Show that $err_S(H_T) \leq \prod_{t=1}^{T} Z_t$, where $err_S(H_T) = \frac{1}{m} \sum_{i=1}^{m} 1_{H_T(x_i) \neq y_i}$ is the training error produced by AdaBoost.

d. Obviously, we would like to minimize test set error produced by AdaBoost, but it is hard to do so directly. We thus settle for greedily optimizing the upper bound on the training error found at part c. Observe that $Z_1, \ldots, Z_{t-1}$ are determined by the first $t-1$ iterations, and we cannot change them at iteration $t$. A greedy step we can take to minimize the training set error bound on round $t$ is to minimize $Z_t$. Prove that the value of $\alpha_t$ that minimizes $Z_t$ (among all possible values for $\alpha_t$) is indeed $\alpha_t = \frac{1}{2} \ln \frac{1 - \epsilon_t}{\epsilon_t}$ (see the previous slide).

e. Show that $\prod_{t=1}^{T} Z_t \leq e^{-2 \sum_{t=1}^{T} \gamma_t^2}$.

f. From part c and d, we know the training error decreases at exponential rate with respect to $T$. Assume that there is a number $\gamma > 0$ such that $\gamma \leq \gamma_t$ for $t = 1, \ldots, T$. (This $\gamma$ is called a guarantee of empirical $\gamma$-weak learnability.) How many rounds are needed to achieve a training error $\epsilon > 0$? Please express in big-$O$ notation, $T = O(\cdot)$. 
Solution

b. We will expand $D_t(i)$ recursively:

\[
D_{T+1}(i) = \frac{1}{Z_T} D_T(i) e^{-\alpha_T y_i h_T(x_i)}
\]

\[
= D_T(i) \frac{1}{Z_T} e^{-\alpha_T y_i h_T(x_i)}
\]

\[
= D_{T-1}(i) \frac{1}{Z_{T-1}} e^{-\alpha_{T-1} y_i h_{T-1}(x_i)} \frac{1}{Z_T} e^{-\alpha_T y_i h_T(x_i)}
\]

\[
\vdots
\]

\[
= D_1(i) \frac{1}{\prod_{t=1}^T Z_t} e^{-\sum_{t=1}^T \alpha_t y_i h_t(x_i)}
\]

\[
= \frac{1}{m \cdot \prod_{t=1}^T Z_t} e^{-y_i f(x_i)}.
\]
c. We will make use of the fact that the exponential loss function upper bounds the 0-1 loss function, i.e. 
\[ 1_{\{x < 0\}} \leq e^{-x} : \]

\[
err_S(H_T) = \frac{1}{m} \sum_{i=1}^{m} 1_{y_i f(x_i) < 0} \\
\leq \frac{1}{m} \sum_{i=1}^{m} e^{-y_i f(x_i)} \\
= \frac{1}{m} \sum_{i=1}^{m} D_{T+1}(i) \cdot m \cdot \prod_{t=1}^{T} Z_t = \sum_{i=1}^{m} D_{T+1}(i) \prod_{t=1}^{T} Z_t \\
= \left( \sum_{i=1}^{m} D_{T+1}(i) \right) \cdot \left( \prod_{t=1}^{T} Z_t \right) \underbrace{1} \\
= \prod_{t=1}^{T} Z_t. 
\]
d. We will start from the equation

\[
Z_t = \varepsilon_t \cdot e^{\alpha_t} + (1 - \varepsilon_t) \cdot e^{-\alpha_t},
\]

which has been proven at part a. Note that the right-hand side is constant with respect to \(\varepsilon_t\) (the error produced by \(h_t\), the hypothesis produced by the weak classifier \(A\) at the current step).

Then we will proceed as usually, computing the partial derivative w.r.t. \(\varepsilon_t\):

\[
\frac{\partial}{\partial \alpha_t} \left( \varepsilon_t \cdot e^{\alpha_t} + (1 - \varepsilon_t) \cdot e^{-\alpha_t} \right) = 0 \iff \varepsilon_t \cdot e^{\alpha_t} - (1 - \varepsilon_t) \cdot e^{-\alpha_t} = 0
\]

\[
\iff \varepsilon_t \cdot (e^{\alpha_t})^2 = 1 - \varepsilon_t \iff e^{2\alpha_t} = \frac{1 - \varepsilon_t}{\varepsilon_t} \iff 2\alpha_t = \ln \left( \frac{1 - \varepsilon_t}{\varepsilon_t} \right) \iff \alpha_t = \frac{1}{2} \ln \left( \frac{1 - \varepsilon_t}{\varepsilon_t} \right).
\]

Note that \(\frac{1 - \varepsilon_t}{\varepsilon_t} > 1\) (and therefore \(\alpha_t > 0\)) because \(\varepsilon_t \in (0, 1/2)\).

It can also be immediately shown that \(\alpha_t = \frac{1}{2} \ln \left( \frac{1 - \varepsilon_t}{\varepsilon_t} \right)\) is indeed the value for which we reach the minim of the expression \(\varepsilon_t \cdot e^{\alpha_t} + (1 - \varepsilon_t) \cdot e^{-\alpha_t}\), and therefore of \(Z_t\) too:

\[
\varepsilon_t \cdot e^{\alpha_t} - (1 - \varepsilon_t) \cdot e^{-\alpha_t} > 0 \iff e^{2\alpha_t} - \frac{1 - \varepsilon_t}{\varepsilon_t} > 0 \iff \alpha_t > \frac{1}{2} \ln \left( \frac{1 - \varepsilon_t}{\varepsilon_t} \right).
\]
Plots of three $Z(\beta)$ functions,

$$Z(\beta) = \varepsilon_t \cdot \beta + (1 - \varepsilon_t) \cdot \frac{1}{\beta}$$

where

$\beta \neq e^\alpha$, ($\alpha$ being free(!) here)

and $\varepsilon_t$ is fix.

It implies that

$$\beta_{\text{min}} = \sqrt{\frac{1 - \varepsilon_t}{\varepsilon_t}}$$

$$Z(\beta_{\text{min}}) = \ldots = 2\sqrt{\varepsilon_t(1 - \varepsilon_t)}$$

$$\alpha_{\text{min}} = \ln \beta_{\text{min}} = \ln \sqrt{\frac{1 - \varepsilon_t}{\varepsilon_t}}$$
e. Making use of the relationship (6) proven at part a, and using the fact that \(1 - x \leq e^{-x}\) for all \(x \in \mathbb{R}\), we can write:

\[
\prod_{t=1}^{T} Z_t = \prod_{t=1}^{T} 2 \cdot \sqrt{\varepsilon_t (1 - \varepsilon_t)} \\
= \prod_{t=1}^{T} 2 \cdot \sqrt{\left(\frac{1}{2} - \gamma_t\right) \left(1 - \left(\frac{1}{2} - \gamma_t\right)\right)} \\
= \prod_{t=1}^{T} \sqrt{1 - 4\gamma_t^2} \\
\leq \prod_{t=1}^{T} e^{-4\gamma_t^2} \\
= \prod_{t=1}^{T} \sqrt{(e^{-2\gamma_t^2})^2} = \prod_{t=1}^{T} e^{-2\gamma_t^2} \\
= e^{-2 \sum_{t=1}^{T} \gamma_t^2}.
\]
From the result obtained at parts c and d, we get:

\[
err_S(H_T) \leq e^{-2\sum_{t=1}^{T} \gamma_t^2} \leq e^{-2T\gamma^2} = \left(e^{-2\gamma^2}\right)^T = \frac{1}{(e^{2\gamma^2})^T}
\]

Therefore,

\[
err_S(H_T) < \varepsilon \text{ if } -2T\gamma^2 < \ln \varepsilon \iff 2T\gamma^2 > -\ln \varepsilon \iff 2T\gamma^2 > \ln \frac{1}{\varepsilon} \iff T > \frac{1}{2\gamma^2} \ln \frac{1}{\varepsilon}
\]

Hence we need \( T = \mathcal{O}\left(\frac{1}{\gamma^2 \ln \frac{1}{\varepsilon}}\right) \).

Note: It follows that \( err_S(H_T) \to 0 \) as \( T \to \infty \).
Exemplifying the application of AdaBoost algorithm

CMU, 2015 fall, Ziv Bar-Joseph, Eric Xing, HW4, pr. 2.6
Consider the training dataset in the nearby figure. Run $T = 3$ iterations of AdaBoost with decision stumps (axis-aligned separators) as the base learners. Illustrate the learned weak hypotheses $h_t$ in this figure and fill in the table given below.

(For the pseudo-code of the AdaBoost algorithm, see CMU, 2015 fall, Ziv Bar-Joseph, Eric Xing, HW4, pr. 2.1-5. Please read the Important Remark that follows that pseudo-code!)

**Note:** The goal of this exercise is to help you understand how AdaBoost works in practice. It is advisable that — after understanding this exercise — you would implement a program / function that calculates the weighted training error produced by a given decision stump, w.r.t. a certain probabilistic distribution ($D$) defined on the training dataset. Later on you will extend this program to a full-fledged implementation of AdaBoost.
Solution

Unlike the graphical representation that we used until now for decision stumps (as trees of depth 1), here we will work with the following analytical representation: for a continuous attribute $X$ taking values $x \in \mathbb{R}$ and for any threshold $s \in \mathbb{R}$, we can define two decision stumps:

$$\text{sign}(x - s) = \begin{cases} 1 & \text{if } x \geq s \\ -1 & \text{if } x < s \end{cases} \quad \text{and} \quad \text{sign}(s - x) = \begin{cases} -1 & \text{if } x \geq s \\ 1 & \text{if } x < s \end{cases}.$$ 

For convenience, in the sequel we will denote the first decision stump with $X \geq s$ and the second with $X < s$.

According to the Important Remark that follows the AdaBoost pseudo-code [see CMU, 2015 fall, Ziv Bar-Joseph, Eric Xing, HW4, pr. 2.1-5], at each iteration ($t$) the weak algorithm $A$ selects the/a decision stump which, among all decision stumps, has the minimum weighted training error w.r.t. the current distribution ($D_t$) on the training data.
Notes

When applying the ID3 algorithm, for each continuous attribute $X$, we used a threshold for each pair of examples $(x_i, y_i), (x_{i+1}, y_{i+1})$, with $y_i y_{i+1} < 0$ such that $x_i < x_{i+1}$, but no $x_j \in Val(X)$ for which $x_i < x_j < x_{i+1}$.

We will proceed similarly when applying AdaBoost with decision stumps and continuous attributes.

[In the case of ID3 algorithm, there is a theoretical result stating that there is no need to consider other thresholds for a continuous attribute $X$ apart from those situated between pairs of successive values $(x_i < x_{i+1})$ having opposite labels $(y_i \neq y_{i+1})$, because the Information Gain (IG) for the other thresholds $(x_i < x_{i+1}, \text{with } y_i = y_{i+1})$ is provably less than the maximal IG for $X$.

LC: A similar result can be proven, which allows us to simplify the application of the weak classifier ($A$) in the framework of the AdaBoost algorithm.]

Moreover, we will consider also a threshold from the outside of the interval of values taken by the attribute $X$ in the training dataset. [The decision stumps corresponding to this “outside” threshold can be associated with the decision trees of depth 0 that we met in other problems.]
Iteration \( t = 1 \):

Therefore, at this stage (i.e., the first iteration of AdaBoost) the \textit{thresholds} for the two continuous variables \((X_1 \text{ and } X_2)\) corresponding to the two coordinates of the training instances \((x_1, \ldots, x_9)\) are

- \( \frac{1}{2}, \frac{5}{2}, \text{ and } \frac{9}{2} \) for \( X_1 \), and
- \( \frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \text{ and } \frac{7}{2} \) for \( X_2 \).

One can easily see that we can get rid of the “outside” threshold \( \frac{1}{2} \) for \( X_2 \), because the decision stumps corresponding to this threshold act in the same as the decision stumps associated to the “outside” threshold \( \frac{1}{2} \) for \( X_1 \).

The \textit{decision stumps} corresponding to this iteration together with their associated \textit{weighted training errors} are shown on the next slide. When filling those tables, we have used the equalities \( \text{err}_{D_t}(X_1 \geq s) = 1 - \text{err}_{D_t}(X_1 < s) \) and, similarly, \( \text{err}_{D_t}(X_2 \geq s) = 1 - \text{err}_{D_t}(X_2 < s) \), for any threshold \( s \) and every iteration \( t = 1, 2, \ldots \). These equalities are easy to prove.

<td>5/9</td>
<td>5/9</td>
<td>2/3</td>
<td>7/9</td>
</tr>
</tbody>
</table>

It can be seen that the minimal weighted training error ($\varepsilon_1 = 2/9$) is obtained for the decision stumps $X_1 < 5/2$ and $X_2 < 7/2$. Therefore we can choose $h_1 = \text{sign}\left(\frac{7}{2} - X_2\right)$ as best hypothesis at iteration $t = 1$; the corresponding separator is the line $X_2 = \frac{7}{2}$. The $h_1$ hypothesis wrongly classifies the instances $x_4$ and $x_5$. Then

$$\gamma_1 = \frac{1}{2} - \frac{2}{9} = \frac{5}{18} \quad \text{and} \quad \alpha_1 = \frac{1}{2} \ln \frac{1 - \varepsilon_1}{\varepsilon_1} = \ln \sqrt{\left(1 - \frac{2}{9}\right) : \frac{2}{9}} = \ln \sqrt{\frac{7}{2}} \approx 0.626$$
Now the algorithm must get a new distribution \( (D_2) \) by altering the old one \( (D_1) \) so that the next iteration concentrates more on the misclassified instances.

\[
D_2(i) = \frac{1}{Z_1} D_1(i) \left( e^{-\alpha_1} \right)^{y_i} h_1(x_i) = \begin{cases} 
\frac{1}{Z_1} \cdot \frac{1}{9} \cdot \sqrt{\frac{2}{7}} & \text{for } i \in \{1, 2, 3, 6, 7, 8, 9\}; \\
\frac{1}{Z_1} \cdot \frac{1}{9} \cdot \sqrt{\frac{7}{2}} & \text{for } i \in \{4, 5\}.
\end{cases}
\]

Remember that \( Z_1 \) is a normalization factor for \( D_2 \).

So,

\[
Z_1 = \frac{1}{9} \left( 7 \cdot \sqrt{\frac{2}{7}} + 2 \cdot \sqrt{\frac{7}{2}} \right) = \frac{2\sqrt{14}}{9} = 0.8315
\]

Therefore,

\[
D_2(i) = \begin{cases} 
\frac{9}{2\sqrt{14}} \cdot \frac{1}{9} \cdot \sqrt{\frac{2}{7}} = \frac{1}{14} & \text{for } i \not\in \{4, 5\}; \\
\frac{9}{2\sqrt{14}} \cdot \frac{1}{9} \cdot \sqrt{\frac{7}{2}} = \frac{1}{4} & \text{for } i \in \{4, 5\}.
\end{cases}
\]
Note

If, instead of \( \text{sign}\left(\frac{7}{2} - X_2\right) \) we would have taken, as hypothesis \( h_1 \), the decision stump \( \text{sign}\left(\frac{5}{2} - X_1\right) \), the subsequent calculus would have been slightly different (although both decision stumps have the same – minimal – weighted training error, \( \frac{2}{9} \)): \( x_8 \) and \( x_9 \) would have been allocated the weights \( \frac{1}{4} \), while \( x_4 \) \& \( x_5 \) would have been allocated the weights \( \frac{1}{14} \).

(Therefore, the output of AdaBoost may not be uniquely determined!)
Iteration $t = 2$:

$$
\begin{array}{|c|ccc|}
\hline
s & \frac{1}{2} & \frac{5}{2} & \frac{9}{2} \\
\hline
err_{D2}(X_1 < s) & \frac{4}{14} & \frac{2}{14} & \frac{2}{14} + \frac{2}{14} + \frac{2}{14} = \frac{11}{14} \\
err_{D2}(X_1 \geq s) & \frac{10}{14} & \frac{12}{14} & \frac{3}{14} \\
\hline
\end{array}
$$

$$
\begin{array}{|c|ccc|}
\hline
s & \frac{1}{2} & \frac{3}{2} & \frac{5}{2} & \frac{7}{2} \\
\hline
err_{D2}(X_2 < s) & \frac{4}{14} & \frac{1}{14} + \frac{3}{14} = \frac{13}{28} & \frac{2}{4} + \frac{1}{14} = \frac{8}{14} & \frac{2}{4} = \frac{1}{2} \\
err_{D2}(X_2 \geq s) & \frac{10}{14} & \frac{15}{28} & \frac{6}{14} & \frac{1}{2} \\
\hline
\end{array}
$$

*Note:* According to the theoretical result presented at part a of CMU, 2015 fall, Ziv Bar-Joseph, Eric Xing, HW4, pr. 2.1-5, computing the weighted error rate of the decision stump [corresponding to the test] $X_2 < \frac{7}{2}$ is now superfluous, because this decision stump has been chosen as optimal hypothesis at the previous iteration. (Nevertheless, we had placed it into the table, for the sake of a thorough presentation.)
Now the best hypothesis is $h_2 = \text{sign}\left(\frac{5}{2} - X_1\right)$; the corresponding separator is the line $X_1 = \frac{5}{2}$.

$$\varepsilon_2 = P_{D_2}\{x_8, x_9\} = \frac{2}{14} = \frac{1}{7} = 0.143 \quad \Rightarrow \gamma_2 = \frac{1}{2} - \frac{1}{7} = \frac{5}{14}$$

$$\alpha_2 = \ln \sqrt{\frac{1 - \varepsilon_2}{\varepsilon_2}} = \ln \sqrt{\left(1 - \frac{1}{7}\right) \cdot \frac{1}{7}} = \ln \sqrt{6} = 0.896$$

$$D_3(i) = \frac{1}{Z_2} \cdot D_2(i) \cdot \left(\frac{e^{-\alpha_2}}{1/\sqrt{6}}\right) y_i h_2(x_i) = \begin{cases} \frac{1}{Z_2} \cdot D_2(i) \cdot \frac{1}{\sqrt{6}} & \text{if } h_2(x_i) = y_i; \\
\frac{1}{Z_2} \cdot D_2(i) \cdot \sqrt{6} & \text{otherwise} \end{cases}$$

$$= \begin{cases} 
\frac{1}{Z_2} \cdot \frac{1}{14} \cdot \frac{1}{\sqrt{6}} & \text{for } i \in \{1, 2, 3, 6, 7\}; \\
\frac{1}{Z_2} \cdot \frac{1}{4} \cdot \frac{1}{\sqrt{6}} & \text{for } i \in \{4, 5\}; \\
\frac{1}{Z_2} \cdot \frac{1}{14} \cdot \sqrt{6} & \text{for } i \in \{8, 9\}. 
\end{cases}$$
\[ Z_2 = 5 \cdot \frac{1}{14} \cdot \frac{1}{\sqrt{6}} + 2 \cdot \frac{1}{4} \cdot \frac{1}{\sqrt{6}} + 2 \cdot \frac{1}{14} \cdot \sqrt{6} = \frac{5}{14\sqrt{6}} + \frac{1}{2\sqrt{6}} + \frac{\sqrt{6}}{7} = \frac{12 + 12}{14\sqrt{6}} = \frac{24}{14\sqrt{6}} = \frac{2\sqrt{6}}{7} \approx 0.7 \]

\[ D_3(i) = \begin{cases} \frac{7}{2\sqrt{6}} \cdot \frac{1}{14} \cdot \frac{1}{\sqrt{6}} = \frac{1}{24} & \text{for } i \in \{1, 2, 3, 6, 7\}; \\
\frac{7}{2\sqrt{6}} \cdot \frac{1}{4} \cdot \frac{1}{\sqrt{6}} = \frac{7}{48} & \text{for } i \in \{4, 5\}; \\
\frac{7}{2\sqrt{6}} \cdot \frac{1}{14} \cdot \sqrt{6} = \frac{1}{4} & \text{for } i \in \{8, 9\}. \end{cases} \]
**Iteration \( t = 3 \):**

<table>

</table>

| $H(x_i)$ | +1 | +1 | −1 | −1 | −1 | −1 | +1 | +1 |
**Remark:** One can immediately see that the [test] instance \((1,4)\) will be classified by the hypothesis \(H\) learned by AdaBoost as negative (since \(-\alpha_1 + \alpha_2 - \alpha_3 = -0.626 + 0.896 - 0.973 < 0\)). After making other similar calculi, we can conclude that the decision zones and the decision boundaries produced by AdaBoost for the given training data will be as indicated in the nearby figure.

![Diagram](image)

**Remark:** The execution of AdaBoost could continue (if we would have taken initially \(T > 3\)...), although we have obtained \(err_S(H) = 0\) at iteration \(t = 3\). By elaborating the details, we would see that for \(t = 4\) we would obtain as optimal hypothesis \(X_2 < 7/2\) (which has already been selected at iteration \(t = 1\)). This hypothesis produces now the weighted training error \(\varepsilon_4 = 1/6\). Therefore, \(\alpha_4 = \ln \sqrt{5}\), and this will be added to \(\alpha_1 = \ln \sqrt{7/2}\) in the new output \(H\). In this way, the confidence in the hypothesis \(X_2 < 7/2\) would be strengthened.

So, we should keep in mind that AdaBoost can select several times a certain weak hypothesis (but never at consecutive iterations, cf. CMU, 2015 fall, E. Xing, Z. Bar-Joseph, HW4, pr. 2.1).
The variation of $\varepsilon_t$ w.r.t. $t$:

AdaBoost and [non] empirical $\gamma$-weak learnability:

Exemplification on a dataset from $\mathbb{R}$

CMU, 2012 fall, Tom Mitchell, Ziv Bar-Joseph, final, pr. 8.a-e
In this problem, we study how AdaBoost performs on a very simple classification problem shown in the nearby figure.

We use decision stump for each weak hypothesis \( h_i \). Decision stump classifier chooses a constant value \( s \) and classifies all points where \( x > s \) as one class and other points where \( x \leq s \) as the other class.

a. What is the initial weight that is assigned to each data point?

b. Show the decision boundary for the first decision stump (indicate the positive and negative side of the decision boundary).

c. Circle the point whose weight increases in the boosting process.

d. Write down the weight that is assigned to each data point after the first iteration of boosting algorithm.

e. Can boosting algorithm perfectly classify all the training examples? If no, briefly explain why. If yes, what is the minimum number of iterations?

$H_4(x_i)$ | − | + | − |

$\Rightarrow err_S(H_4) = 1/3$

It can be easily proven that the signs of $x_1$ and $x_3$ will always be opposite to each other, while the sign of $x_2$ will always be +.

Therefore $err_S(H_T) = 1/3$ for any $T \in \mathbb{N}^*$. 
Graphs made by Sebastian Ciobanu
Seeing AdaBoost as an *optimization algorithm*, w.r.t. the [negative] exponential *loss function*

CMU, 2008 fall, Eric Xing, HW3, pr. 4.1.1
CMU, 2008 fall, Eric Xing, midterm, pr. 5.1
At CMU, 2015 fall, Ziv Bar-Joseph, Eric Xing, HW4, pr. 2.1-5, part d, we have shown that in AdaBoost, we try to [indirectly] minimize the training error $\text{err}_S(H)$ by sequentially minimizing its upper bound $\prod_{t=1}^{T} Z_t$, i.e. at each iteration $t$ ($1 \leq t \leq T$) we choose $\alpha_t$ so as to minimize $Z_t$ (viewed as a function of $\alpha_t$).

Here you will see that another way to explain AdaBoost is by sequentially minimizing the negative exponential loss:

$$ J_T \overset{\text{def.}}{=} \frac{1}{m} \sum_{i=1}^{m} \exp(-y_if_T(x_i)) = \frac{1}{m} \sum_{i=1}^{m} \exp(-y_i \sum_{t=1}^{T} \alpha_t h_t(x_i)). \quad (8) $$

That is to say, at the $t$-th iteration ($1 \leq t \leq T$) we want to choose besides the appropriate classifier $h_t$ the corresponding weight $\alpha_t$ so that the overall loss $J_t$ (accumulated up to the $t$-th iteration) is minimized.

Prove that this [new] strategy will lead to the same update rule for $\alpha_t$ used in AdaBoost, i.e., $\alpha_t = \frac{1}{2} \ln \frac{1 - \varepsilon_t}{\varepsilon_t}$.

**Hint:** You can use the fact that $D_t(i) \propto \exp(-y_i f_{t-1}(x_i))$, and it [LC: the proportionality factor] can be viewed as constant when we try to optimize $J_t$ with respect to $\alpha_t$ in the $t$-th iteration.
Solution

At the $t$-th iteration, we have

$$J_t = \frac{1}{m} \sum_{i=1}^{m} \exp(-y_if_t(x_i)) = \frac{1}{m} \sum_{i=1}^{m} \exp\left(-y_i \left(\sum_{t' = 1}^{t-1} \alpha_{t'} h_{t'}(x_i)\right) - y_i \alpha_t h_t(x_i)\right)$$

$$= \frac{1}{m} \sum_{i=1}^{m} \exp(-y_if_{t-1}(x_i)) \cdot \exp(-y_i \alpha_t h_t(x_i)) = \frac{1}{m} \sum_{i=1}^{m} \left( m \prod_{i=1}^{t-1} Z_t \right) \cdot D_t(i) \cdot \exp(-y_i \alpha_t h_t(x_i))$$

$$\propto \sum_{i=1}^{m} D_t(i) \cdot \exp(-y_i \alpha_t h_t(x_i)) \overset{not}{=} J'_t \text{ (see CMU, 2015 fall, Z. Bar-Joseph, E. Xing, HW4, pr. 2.1-5, part b)}$$

Further on, we can rewrite $J'_t$ as

$$J'_t = \sum_{i=1}^{m} D_t(i) \cdot \exp(-y_i \alpha_t h_t(x_i)) = \sum_{i \in C} D_t(i) \exp(-\alpha_t) + \sum_{i \in M} D_t(i) \exp(\alpha_t)$$

$$= (1 - \varepsilon_t) \cdot e^{-\alpha_t} + \varepsilon_t \cdot e^{\alpha_t}, \quad (9)$$

where $C$ is the set of examples which are correctly classified by $h_t$, and $M$ is the set of examples which are mis-classified by $h_t$. 
The relation (9) is identical with the expression (3) from part a of CMU, 2015 fall, Ziv Bar-Joseph, Eric Xing, HW4, pr. 2.1-5 (see the solution). Therefore, when $\varepsilon_t$ is fixed, $J_t$ will reach its minim for $\alpha_t = \frac{1}{2} \ln \frac{1 - \varepsilon_t}{\varepsilon_t}$. 

\[ \text{(9)} \] 
\[ \text{(3)} \]
Graph made for the $J'_t$ functions by Sebastian Ciobanu

for CMU, 2015 fall,
Z. Bar-Joseph, E. Xing
HW4, pr. 2.6

(Notation: $\beta = e^\alpha$)
Important Remark  
(in Romanian)

Dacă rescriem expresia (9) sub forma

\[ e^{-\alpha t} + \varepsilon_t \left( e^{\alpha t} - e^{-\alpha t} \right), \]

se observă că dacă fixăm \( \alpha_t \) atunci a minimiza expresia \( J_t \) în raport cu [alegera lui] \( h_t \) revine la a minimiza \( \varepsilon_t \) (care nu depinde de \( \alpha_t \)).

În consecință, algoritmul AdaBoost poate fi reformulat ca un algoritm de optimizare secvențială a costurilor / ,,pierderilor“ \( J_t \).

**Input:** \( \{(x_i, y_i)\}_{i=1,...,m} \) – the training dataset, \( T \) – the number of iterations to be executed, \( \mathcal{H} \) – the set of weak hypotheses, \( \phi(y, y') = \exp(-yy') \) – the exponential loss function.

**Procedure:**

1. Initialize the classifier \( f_0(x) = 0 \) and calculate the distribution \( D_1(i) = 1/m \) for \( i = 1, \ldots, m \)
2. For \( t = 1 \) to \( T \) do:
   1. Compute
   \[
   (h_t, \alpha_t) = \arg\min_{h \in \mathcal{H}, \alpha \in \mathbb{R}} \sum_{i=1}^{m} \phi(y_i, f_{t-1}(x_i) + \alpha h(x_i)) \]
   \[
   J_t(h, \alpha) = J_{t-1}(h) + \alpha \sum_{i=1}^{m} \phi(y_i, f_{t-1}(x_i) + \alpha h(x_i)) \]
   2. Update the classifier \( f_t(x) = f_{t-1}(x) + \alpha_t h_t(x) \) and calculate the new distribution, \( D_{t+1} \)
3. Return the classifier \( \text{sign}(f_T(x)) \)

The intuition is that, at each step, the algorithm greedily adds a hypothesis \( h \in \mathcal{H} \) to the current hypothesis to minimize the \( \phi \)-risk.
AdaBoost algorithm: the notion of \([voting] \text{ margin}\); some properties

CMU, 2016 spring, W. Cohen, N. Balcan, HW4, pr. 3.3
Despite that model complexity increases with each iteration, AdaBoost does not usually overfit. The reason behind this is that the model becomes more “confident” as we increase the number of iterations. The “confidence” can be expressed mathematically as the [voting] margin. Recall that after the algorithm AdaBoost terminates with \( T \) iterations the [output] classifier is

\[
H_T(x) = \text{sign} \left( \sum_{t=1}^{T} \alpha_t h_t(x) \right).
\]

Similarly, we can define the intermediate weighted classifier after \( k \) iterations as:

\[
H_k(x) = \text{sign} \left( \sum_{t=1}^{k} \alpha_t h_t(x) \right).
\]

As its output is either \(-1\) or \(1\), it does not tell the confidence of its judgement. Here, without changing the decision rule, let

\[
H_k(x) = \text{sign} \left( \sum_{t=1}^{k} \tilde{\alpha}_t h_t(x) \right),
\]

where \( \tilde{\alpha}_t = \frac{\alpha_t}{\sum_{t'=1}^{k} \alpha_{t'}} \) so that the weights on each weak classifier are normalized.
Define the **margin** after the $k$-th iteration as [the sum of] the [normalized] weights of $h_t$ voting correctly minus [the sum of] the [normalized] weights of $h_t$ voting incorrectly.

$$\text{Margin}_k(x) = \sum_{t: h_t(x) = y} \bar{\alpha}_t - \sum_{t: h_t(x) \neq y} \bar{\alpha}_t.$$ 

a. Let $f_k(x) \not= \sum_{t=1}^{k} \bar{\alpha}_t h_t(x)$. Show that $\text{Margin}_k(x_i) = y_i f_k(x_i)$ for all training instances $x_i$, with $i = 1, \ldots, m$.

b. If $\text{Margin}_k(x_i) > \text{Margin}_k(x_j)$, which of the samples $x_i$ and $x_j$ will receive a higher weight in iteration $k + 1$?

**Hint:** Use the relation $D_{k+1}(i) = \frac{1}{m \cdot \prod_{t=1}^{k} Z_t} \cdot \exp(-y_i f_k(x_i))$ which was proven at CMU, 2015 fall, Z. Bar-Joseph, E. Xing, HW4, pr. 2.2.
Solution

a. We will prove the equality starting from its right hand side:

\[ y_i f_k(x_i) = y_i \sum_{t=1}^{k} \alpha_t h_t(x_i) = \sum_{t=1}^{k} \alpha_t y_i h_t(x_i) = \sum_{t:h_t(x_i)=y_i} \alpha_t - \sum_{t:h_t(x_i) \neq y_i} \alpha_t = \text{Margin}_k(x_i). \]

b. According to the relationship already proven at part a,

\[ \text{Margin}_k(x_i) > \text{Margin}_k(x_j) \iff y_i f_k(x_i) > y_j f_k(x_j) \iff -y_i f_k(x_i) < -y_j f_k(x_j) \iff \exp(-y_i f_k(x_i)) < \exp(-y_j f_k(x_j)). \]

Based on the given Hint, it follows that \( D_{k+1}(i) < D_{k+1}(j). \)
Important Remark

It can be shown that boosting tends to increase the margins of training examples — see the relation (8) at CMU, 2008 fall, Eric Xing, HW3, pr. 4.1.1 —, and that a large margin on training examples reduces the generalization error.

Thus we can explain why, although the number of “parameters” of the model created by AdaBoost increases with 2 at every iteration — therefore complexity rises —, it usually doesn’t overfit.
AdaBoost: a sufficient condition for $\gamma$-weak learnability, based on the voting margins

CMU, 2016 spring, W. Cohen, N. Balcan, HW4, pr. 3.1.4
At CMU, 2015 fall, Z. Bar-Joseph, E. Xing, HW4, pr. 2.5 we encountered the notion of empirical $\gamma$-weak learnability. When this condition — $\gamma \leq \gamma_t$ for all $t$, where $\gamma_t \overset{\text{def.}}{=} \frac{1}{2} - \varepsilon_t$, with $\varepsilon_t$ being the weighted training error produced by the weak hypothesis $h_t$ — is met, it ensures that AdaBoost will drive down the training error quickly. However, this condition does not hold all the time.

In this problem we will prove a sufficient condition for empirical weak learnability [to hold]. This condition refers to the notion of voting margin which was presented in CMU, 2016 spring, W. Cohen, N. Balcan, HW4, pr. 3.3.

Namely, we will prove that if there is a constant $\theta > 0$ such that the [voting] margins of all training instances are lower-bounded by $\theta$ at each iteration of the AdaBoost algorithm, then the property of empirical $\gamma$-weak learnability is “guaranteed”, with $\gamma = \theta/2$. 
[Formalisation]

Suppose we are given a training set $S = \{(x_1, y_1), \ldots, (x_m, y_m)\}$, such that for some weak hypotheses $h_1, \ldots, h_k$ from the hypothesis space $H$, and some non-negative coefficients $\alpha_1, \ldots, \alpha_k$ with $\sum_{j=1}^{k} \alpha_j = 1$, there exists $\theta > 0$ such that

$$y_i \left( \sum_{j=1}^{k} \alpha_j h_j(x_i) \right) \geq \theta, \ \forall (x_i, y_i) \in S.$$

Note: according to CMU, 2016 spring, W. Cohen, N. Balcan, HW4, pr. 3.3,

$$y_i \left( \sum_{j=1}^{k} \alpha_j h_j(x_i) \right) = \text{Margin}_k(x_i) = f_k(x_i), \text{ where } f_k(x_i) = \sum_{j=1}^{k} \alpha_j h_j(x_i).$$

Key idea: We will show that if the condition above is satisfied (for a given $k$), then for any distribution $D$ over $S$, there exists a hypothesis $h_l \in \{h_1, \ldots, h_k\}$ with weighted training error at most $\frac{1}{2} - \frac{\theta}{2}$ over the distribution $D$.

It will follow that when the condition above is satisfied for any $k$, the training set $S$ is empirically $\gamma$-weak learnable, with $\gamma = \frac{\theta}{2}$. 
a. Show that — if the condition stated above is met — there exists a weak hypothesis \( h_l \) from \( \{h_1, \ldots, h_k\} \) such that \( E_{i \sim D}[y_i h_l(x_i)] \geq \theta \).

**Hint:** Taking expectation under the same distribution does not change the inequality conditions.

b. Show that the inequality \( E_{i \sim D}[y_i h_l(x_i)] \geq \theta \) is equivalent to

\[
\Pr_{i \sim D}[y_i \neq h_l(x_i)] \leq \frac{1}{2} - \frac{\theta}{2},
\]

meaning that the weighted training error of \( h_l \) is at most \( \frac{1}{2} - \frac{\theta}{2} \), and therefore \( \gamma_t \geq \frac{\theta}{2} \).
Solution

a. Since $y_i(\sum_{j=1}^{k} \alpha_j h_j(x_i)) \geq \theta \iff y_i f_k(x_i) \geq \theta$ for $i = 1, \ldots, m$, it follows (according to the Hint) that

$$E_{i \sim D}[y_i f_k(x_i)] \geq \theta \text{ where } f_k(x_i) \overset{\text{not.}}{=} \sum_{j=1}^{k} \alpha_j h_j(x_i). \quad (10)$$

On the other side, $E_{i \sim D}[y_i h_l(x_i)] \geq \theta \iff \sum_{i=1}^{m} y_i h_l(x_i) \cdot D(i) \geq \theta$.

Suppose, on contrary, that $E_{i \sim D}[y_i h_l(x_i)] < \theta$, that is $\sum_{i=1}^{m} y_i h_l(x_i) \cdot D(i) < \theta$ for $l = 1, \ldots, k$. Then $\sum_{i=1}^{m} y_i h_l(x_i) \cdot D(i) \cdot \alpha_l < \theta \cdot \alpha_l$ for $l = 1, \ldots, k$. By summing up these inequations for $l = 1, \ldots, k$ we get

$$\sum_{l=1}^{k} \sum_{i=1}^{m} y_i h_l(x_i) \cdot D(i) \cdot \alpha_l < \sum_{l=1}^{k} \theta \cdot \alpha_l \iff \sum_{i=1}^{m} y_i D(i) \left( \sum_{l=1}^{k} h_l(x_i) \alpha_l \right) < \theta \sum_{l=1}^{k} \alpha_l \iff$$

$$\sum_{i=1}^{m} y_i f_k(x_i) \cdot D(i) < \theta,$$

because $\sum_{j=1}^{k} \alpha_j = 1 \iff f_k(x_i) \overset{\text{not.}}{=} \sum_{l=1}^{k} \alpha_l h_l(x_i)$.

The inequation (11) can be written as $E_{i \sim D}[y_i f_k(x_i)] < \theta$. Obviously, it contradicts the relationship (10). Therefore, the previous supposition is false. In conclusion, there exist $l \in \{1, \ldots, k\}$ such that $E_{i \sim D}[y_i h_l(x_i)] \geq \theta$. 

Solution (cont’d)

b. We already said that $E_{i \sim D}[y_i h_l(x_i)] \geq \theta \iff \sum_{i=1}^{m} y_i h_l(x_i) \cdot D(i) \geq \theta$. Since $y_i \in \{-1, +1\}$ and $h_l(x_i) \in \{-1, +1\}$ for $i = 1, \ldots, m$ and $l = 1, \ldots, k$, we have

$$
\sum_{i=1}^{m} y_i h_l(x_i) \cdot D(i) \geq \theta \iff \sum_{i:y_i=h_l(x_i)} D(x_i) - \sum_{i:y_i \neq h_l(x_i)} D(x_i) \geq \theta \iff (1 - \varepsilon_l) - \varepsilon_l \geq \theta \iff
$$

$$
1 - 2\varepsilon_l \geq \theta \iff 2\varepsilon_l \leq 1 - \theta \iff \varepsilon_l \leq \frac{1}{2} - \frac{\theta}{2} \overset{\text{def.}}{\iff} \text{err}_D(h_l) \leq \frac{1}{2} - \frac{\theta}{2}.
$$

for CMU, 2006 spring, Carlos Guestrin, final, pr. 3
AdaBoost:
Any set of consistently labelled instances from $\mathbb{R}$
is empirically $\gamma$-weak learnable
by using decision stumps

Stanford, 2016 fall, Andrew Ng, John Duchi, HW2, pr. 6.abc
At CMU, 2015, Z. Bar-Joseph, E. Xing, HW4, pr. 2.5 we encountered the notion of empirical $\gamma$-weak learnability. When this condition — $\gamma \leq \gamma_t$ for all $t$, where $\gamma_t \overset{\text{def.}}{=} \frac{1}{2} - \varepsilon_t$, with $\varepsilon_t$ being the weighted training error produced by the weak hypothesis $h_t$ — is met, it ensures that AdaBoost will drive down the training error quickly.

In this problem we will assume that our input attribute vectors $x \in \mathbb{R}$, that is, they are one-dimensional, and we will show that [LC] when these vectors are consistently labelled, decision stumps based on thresholding provide a weak-learning guarantee ($\gamma$).
Decision stumps: analytical definitions / formalization

Thresholding-based decision stumps can be seen as functions indexed by a threshold $s$ and sign $+/−$, such that

$$\phi_{s,+}(x) = \begin{cases} 
1 & \text{if } x \geq s \\
-1 & \text{if } x < s 
\end{cases} \quad \text{and} \quad \phi_{s,-}(x) = \begin{cases} 
-1 & \text{if } x \geq s \\
1 & \text{if } x < s .
\end{cases}$$

Therefore, $\phi_{s,+}(x) = -\phi_{s,-}(x)$.

Key idea for the proof

We will show that given a consistently labelled training set $S = \{(x_1, y_1), \ldots, (x_m, y_m)\}$, with $x_i \in \mathbb{R}$ and $y_i \in \{-1, +1\}$ for $i = 1, \ldots, m$, there is some $\gamma > 0$ such that for any distribution $p$ defined on this training set there is a threshold $s \in \mathbb{R}$ for which

$$\text{error}_p(\phi_{s,+}) \leq \frac{1}{2} - \gamma \quad \text{or} \quad \text{error}_p(\phi_{s,-}) \leq \frac{1}{2} - \gamma,$$

where $\text{error}_p(\phi_{s,+})$ and $\text{error}_p(\phi_{s,-})$ denote the weighted training error of $\phi_{s,+}$ and respectively $\phi_{s,-}$, computed according to the distribution $p$. 
Convention: In our problem we will assume that our training instances $x_1, \ldots, x_m \in \mathbb{R}$ are distinct. Moreover, we will assume (without loss of generality, but this makes the proof notationally simpler) that

$$x_1 > x_2 > \ldots > x_m.$$  

a. Show that, given $S$, for each threshold $s \in \mathbb{R}$ there is some $m_0(s) \in \{0, 1, \ldots, m\}$ such that

$$\text{error}_p(\phi_{s,+}) \overset{\text{def.}}{=} \sum_{i=1}^{m} p_i \cdot 1\{y_i \neq \phi_{s,+}(x_i)\} = \frac{1}{2} - \frac{1}{2} \left( \sum_{i=1}^{m_0(s)} y_ip_i - \sum_{i=m_0(s)+1}^{m} y_ip_i \right)$$

and

$$\text{error}_p(\phi_{s,-}) \overset{\text{def.}}{=} \sum_{i=1}^{m} p_i \cdot 1\{y_i \neq \phi_{s,-}(x_i)\} = \frac{1}{2} - \frac{1}{2} \left( \sum_{i=m_0(s)+1}^{m} y_ip_i - \sum_{i=1}^{m} y_ip_i \right)$$

Note: Treat sums over empty sets of indices as zero. Therefore, $\sum_{i=1}^{0} a_i = 0$ for any $a_i$, and similarly $\sum_{i=m+1}^{m} a_i = 0$.  

131.
b. Prove that, given $S$, there is some $\gamma > 0$ (which may depend on the training set size $m$) such that for any set of probabilities $p$ on the training set (therefore $p_i \geq 0$ and $\sum_{i=1}^{m} p_i = 1$) we can find $m_0 \in \{0, \ldots, m\}$ so as

$$|f(m_0)| \geq 2\gamma,$$

where $f(m_0) = \sum_{i=1}^{m_0} y_i p_i - \sum_{i=m_0+1}^{m} y_i p_i$.

*Note:* $\gamma$ should not depend on $p$.

*Hint:* Consider the difference $f(m_0) - f(m_0 - 1)$.

What is your $\gamma$?
c. Based on your answers to parts a and b, what edge can thresholded decision stumps guarantee on any training set \( \{x_i, y_i\}_{i=1}^m \), where the instances \( x_i \in \mathbb{R} \) are all distinct? Recall that the edge of a weak classifier \( \phi : \mathbb{R} \to \{-1, 1\} \) is the constant \( \gamma \in (0, 1/2) \) such that

\[
\text{error}_p(\phi) \overset{\text{def.}}{=} \sum_{i=1}^m p_i \cdot 1_{\{\phi(x_i) \neq y_i\}} \leq \frac{1}{2} - \gamma.
\]

d. Can you give an upper bound on the number of thresholded decision stumps required to achieve zero error on a given training set?
Solution

a. We perform several algebraic steps.
Let $\text{sign}(t) = 1$ if $t \geq 0$, and $\text{sign}(t) = -1$ otherwise.

Then

$$1\{\phi_s,+(x) \neq y\} = 1\{\text{sign}(x-s) \neq y\} = 1\{y \cdot \text{sign}(x-s) \leq 0\},$$

where the symbol $1\{\}$ denotes the well known indicator function.

Thus we have

$$\text{error}_p(\phi_{s,+}) \overset{\text{def.}}{=} \sum_{i=1}^{m} p_i \cdot 1\{y_i \neq \phi_{s,+}(x_i)\} = \sum_{i=1}^{m} p_i \cdot 1\{y_i \cdot \text{sign}(x_i-s) \leq 0\}$$

$$= \sum_{i:x_i \geq s} p_i \cdot 1\{y_i = -1\} + \sum_{i:x_i < s} p_i \cdot 1\{y_i = 1\}$$

Thus, if we let $m_0(s)$ be the index in $\{0, \ldots, m\}$ such that $x_i \geq s$ for $i \leq m_0(s)$ and $x_i < s$ for $i > m_0(s)$, which we know must exist because $x_1 > x_2 > \ldots$, we have

$$\text{error}_p(\phi_{s,+}) \overset{\text{def.}}{=} \sum_{i=1}^{m} p_i \cdot 1\{y_i \neq \phi_{s,+}(x_i)\} = \sum_{i=1}^{m_0(s)} p_i \cdot 1\{y_i = -1\} + \sum_{i=m_0(s)+1}^{m} p_i \cdot 1\{y_i = 1\}.$$
Now we make a key observation: we have
\[ 1\{y=-1\} = \frac{1-y}{2} \quad \text{and} \quad 1\{y=1\} = \frac{1+y}{2}, \]
because \( y \in \{-1, 1\} \).

Consequently,
\[
\text{error}_p(\phi_{s,+}) \overset{\text{def.}}{=} \sum_{i=1}^{m} p_i \cdot 1\{y_i \neq \phi_{s,+}(x_i)\} = \sum_{i=1}^{m_0(s)} p_i \cdot 1\{y_i=-1\} + \sum_{i=m_0(s)+1}^{m} p_i \cdot 1\{y_i=1\} \\
= \frac{m_0(s)}{2} \sum_{i=1}^{m} p_i \cdot \frac{1-y_i}{2} + \frac{m_0(s)}{2} \sum_{i=m_0(s)+1}^{m} p_i \cdot \frac{1+y_i}{2} = \frac{1}{2} \sum_{i=1}^{m} p_i - \frac{1}{2} \sum_{i=m_0(s)+1}^{m} p_i y_i + \frac{1}{2} \sum_{i=m_0(s)+1}^{m} p_i y_i \\
= \frac{1}{2} - \frac{1}{2} \left( \sum_{i=1}^{m_0(s)} p_i y_i - \sum_{i=m_0(s)+1}^{m} p_i y_i \right).
\]
The last equality follows because \( \sum_{i=1}^{m} p_i = 1 \).

The case for \( \phi_{s,-} \) is symmetric to this one, so we omit the argument.
Solution (cont’d)

b. For any \( m_0 \in \{1, \ldots, m\} \) we have

\[
f(m_0) - f(m_0 - 1) = \sum_{i=1}^{m_0} y_i p_i - \sum_{i=m_0+1}^{m} y_i p_i - \sum_{i=1}^{m_0-1} y_i p_i + \sum_{i=m_0}^{m} y_i p_i = 2y_{m_0} p_{m_0}.
\]

Therefore, \( |f(m_0) - f(m_0 - 1)| = 2|y_{m_0}| p_{m_0} = 2p_{m_0} \) for all \( m_0 \in \{1, \ldots, m\} \).

Because \( \sum_{i=1}^{m} p_i = 1 \), there must be at least one index \( m'_0 \) with \( p_{m'_0} \geq \frac{1}{m} \).

Thus we have \( |f(m'_0) - f(m'_0 - 1)| \geq \frac{2}{m} \), and so it must be the case that at least one of

\[
|f(m'_0)| \geq \frac{1}{m} \quad \text{or} \quad |f(m'_0 - 1)| \geq \frac{1}{m}
\]

holds.

Depending on which one of those two inequations is true, we would then “return” \( m'_0 \) or \( m'_0 - 1 \).

(Note: If \( |f(m'_0 - 1)| \geq \frac{1}{m} \) and \( m'_0 = 1 \), then we have to consider an “outside” threshold, \( s > x_1 \).)

Finally, we have \( \gamma = \frac{1}{2m} \).
c. The inequation proven at part b, namely \(|f(m_0)| \geq 2\gamma\) implies that either \(f(m_0) \geq 2\gamma\) or \(f(m_0) \leq -2\gamma\). So,

\[
\text{either } f(m_0) \geq 2\gamma \iff -f(m_0) \leq -2\gamma \iff \frac{1}{2} - \frac{1}{2} f(m_0) \leq \frac{1}{2} - \frac{1}{2} \cdot 2\gamma = \frac{1}{2} - \gamma \\
\text{or } f(m_0) \leq -2\gamma \iff \frac{1}{2} + \frac{1}{2} f(m_0) \leq \frac{1}{2} - \frac{1}{2} \cdot 2\gamma = \frac{1}{2} - \gamma
\]

for any \(s \in (x_{m_0+1}, x_{m_0}]\),\(^a\)

Therefore thresholded decision stumps are \textit{guaranteed} to have an \textit{edge} of at least \(\gamma = \frac{1}{2m}\) over random guessing.

\(^a\)In the case described by the \textit{Note} at part b, we must consider \(s > x_1\), that is \(s \in (x_1, +\infty)\).
Summing up

At each iteration $t$ executed by AdaBoost,

- a probabilistic distribution $p$ (denoted as $D_t$ in CMU, 2015, Z. Bar-Joseph, E. Xing, HW4, pr. 2.1-5) is in use;
- [at part $b$ of the present exercise we proved that] there is at least one $m_0$ (better denoted $m_0(p)$) in $\{0, \ldots, m\}$ such that

$$|f(m_0)| \geq \frac{1}{m} \text{ not. } 2\gamma,$$

where

$$f(m_0) \overset{\text{def.}}{=} \sum_{i=1}^{m_0} y_ip_i - \sum_{i=m_0+1}^{m} y_ip_i$$

- [the proof made at parts $a$ and $c$ of the present exercise implies that]

  for any $s \in (x_{m_0+1}, x_{m_0}]$, $^a$

$$\text{error}_p(\phi_{s,+}) \leq \frac{1}{2} - \gamma \text{ or error}_p(\phi_{s,-}) \leq \frac{1}{2} - \gamma,$$

where $\gamma = \frac{1}{2m}$.

As a consequence, AdaBoost can choose at each iteration a weak hypothesis $(h_t)$ for which $\gamma_t \geq \gamma = \frac{1}{2m}$.

$^a$See the previous footnote.
Solution (cont’d)

d. Boosting takes \(\frac{\ln m}{2\gamma^2}\) iterations to achieve zero [training] error, as shown at CMU, 2015, Z. Bar-Joseph, E. Xing, HW4, pr. 2.5, so with decision stumps we will achieve zero [training] error in at most \(2m^2 \ln m\) iterations of boosting. Each iteration of boosting introduces a single new weak hypothesis, so at most \(2m^2 \ln m\) thresholded decision stumps are necessary.
A generalized version of the AdaBoost algorithm

MIT, 2003 fall, Tommy Jaakkola, HW4, pr. 2.1-3
Here we derive a boosting algorithm from a slightly more general perspective than the AdaBoost algorithm in CMU, 2015 fall, Z. Bar-Joseph, E. Xing, HW4, pr. 2.1-5, that will be applicable for a class of loss functions including the exponential one.

The goal is to generate discriminant functions of the form

$$f_T(x) = \alpha_1 h(x; \theta_1) + \ldots + \alpha_T h(x; \theta_T),$$

where both $x$ belong to $\mathbb{R}^d$, $\theta$ are parameters, and you can assume that the weak classifiers $h(x; \theta)$ are decision stumps whose predictions are ±1; any other set of weak learners would be fine without modification.

We successively add components to the overall discriminant function in a manner that will separate the estimation of [the parameters of] the weak classifiers from the setting of the votes $\alpha$ to the extent possible.
A useful definition

Let’s start by defining a set of useful loss functions. The only restriction we place on the loss is that it should be a monotonically decreasing and differentiable function of its argument. The argument in our context is $y_i f_T(x_i)$ so that the more the discriminant function agrees with the ±1 label $y_i$, the smaller the loss.

The simple exponential loss we have already considered [at CMU, 2015 fall, Z. Bar-Joseph, E. Xing, HW4, pr. 2.1-5], i.e.,

$$\text{Loss}(y_i f_T(x_i)) = \exp(-y_i f_T(x_i))$$

certainly conforms to this notion.

And so does the logistic loss

$$\begin{align*}
\text{Loss}(y_i f_T(x_i)) &= \ln(1 + \exp(-y_i f_T(x_i))).
\end{align*}$$
Remark

Note that the logistic loss has a nice interpretation as a negative log-probability. Indeed, [recall that] for an additive logistic regression model

$$-\ln P(y = 1|x, w) = -\ln \frac{1}{1 + \exp(-z)} = \ln (1 + \exp(-z)),$$

where $z = w_1\phi_1(x) + \ldots + w_T\phi_T(x)$ and we omit the bias term ($w_0$) for simplicity.

By replacing the additive combination of basis functions ($\phi_i(x)$) with the combination of weak classifiers ($h(x; \theta_i)$), we have an additive logistic regression model where the weak classifiers serve as the basis functions. The difference is that both the basis functions (weak classifiers) and the coefficients multiplying them will be estimated. In the logistic regression model we typically envision a fixed set of basis functions.
Let us now try to derive the boosting algorithm in a manner that can accommodate any loss function of the type discussed above. To this end, at the current iteration \( t \) we suppose that we have already included \( t-1 \) component classifiers

\[
f_{t-1}(x) = \alpha_1 h(x; \hat{\theta}_1) + \ldots + \alpha_{t-1} h(x; \hat{\theta}_{t-1}),
\]

and we wish to add another \( h(x; \theta) \). The estimation criterion for the overall discriminant function, including the new component with votes \( \alpha \), is given by

\[
J_t(\alpha, \theta) = \frac{1}{m} \sum_{i=1}^{m} \text{Loss}(y_i f_{t-1}(x_i) + y_i \alpha h(x_i; \theta)).
\]

Note that we explicate only how the objective depends on the choice of the last component and the corresponding votes since the parameters of the \( t-1 \) previous components along with their votes have already been set and won’t be modified further.
We will first try to find the new component or parameters $\theta$ so as to maximize its potential in reducing the empirical loss, potential in the sense that we can subsequently adjust the votes to actually reduce the empirical loss. More precisely, we set $\theta$ so as to minimize the derivative

$$\frac{\partial}{\partial \alpha} J_t(\alpha, \theta)_{\alpha=0} = \frac{1}{m} \sum_{i=1}^{m} \frac{\partial}{\partial \alpha} \text{Loss}(y_i f_{t-1}(x_i) + y_i \alpha h(x_i; \theta))_{\alpha=0}$$

$$= \frac{1}{m} \sum_{i=1}^{m} dL(y_i f_{t-1}(x_i)) y_i h(x_i; \theta), \quad (13)$$

where $dL(z) \not= \frac{\partial \text{Loss}(z)}{\partial z}$.

Note that this derivative $\frac{\partial}{\partial \alpha} J_t(\alpha, \theta)_{\alpha=0}$ precisely captures the amount by which we would start to reduce the empirical loss if we gradually increased the vote ($\alpha$) for the new component with parameters $\theta$. Minimizing this reduction seems like a sensible estimation criterion for the new component or $\theta$. This plan permits us to first set $\theta$ and then subsequently optimize $\alpha$ to actually minimize the empirical loss.
Let’s rewrite the algorithm slightly to make it look more like a boosting algorithm. First, let’s define the following weights and normalized weights on the training examples:

\[
W_i^{(t-1)} = -dL(y_i f_{t-1}(x_i)), \quad \text{for and}
\]

\[
\tilde{W}_i^{(t-1)} = \frac{W_i^{(t-1)}}{\sum_{j=1}^{m} W_j^{(t-1)}}, \quad \text{for } i = 1, \ldots, m.
\]

These weights are guaranteed to be non-negative since the loss function is a decreasing function of its argument (its derivative has to be negative or zero).
Now we can rewrite the expression (13) as

\[
\frac{\partial}{\partial \alpha} J_t(\alpha, \theta)_{\alpha=0} = -\frac{1}{m} \sum_{i=1}^{m} W_i^{(t-1)} y_i h(x_i; \theta)
\]

\[
= -\frac{1}{m} \left( \sum_j W_j^{(t-1)} \right) \cdot \sum_{i=1}^{m} \frac{W_i^{(t-1)}}{\sum_j W_j^{(t-1)}} y_i h(x_i; \theta)
\]

\[
= -\frac{1}{m} \left( \sum_j W_j^{(t-1)} \right) \cdot \sum_{i=1}^{m} \tilde{W}_i^{(t-1)} y_i h(x_i; \theta).
\]

By ignoring the multiplicative constant (i.e., \( \frac{1}{m} \sum_j W_j^{(t-1)} \), which is constant at iteration \( t \)), we will estimate \( \theta \) by minimizing

\[
- \sum_{i=1}^{m} \tilde{W}_i^{(t-1)} y_i h(x_i; \theta),
\]

(14)

where the normalized weights \( \tilde{W}_i^{(t-1)} \) sum to 1. (This is the same as maximizing the weighted agreement with the labels, i.e., \( \sum_{i=1}^{m} \tilde{W}_i^{(t-1)} y_i h(x_i; \theta) \).)
Some remarks (by Liviu Ciortuz)

1. Using some familiar notations, we can write

\[
\sum_{i=1}^{m} \tilde{W}_{i}^{(t-1)} y_{i} h(x_{i}; \theta) = \sum_{i \in C} \tilde{W}_{i}^{(t-1)} y_{i} h(x_{i}; \theta) + \sum_{i \in M} \tilde{W}_{i}^{(t-1)} y_{i} h(x_{i}; \theta)
\]

\[
= \sum_{i \in C} \tilde{W}_{i}^{(t-1)} - \sum_{i \in M} \tilde{W}_{i}^{(t-1)} = 1 - 2 \varepsilon_{t}
\]

\[
\Rightarrow \varepsilon_{t} = \frac{1}{2} \left( 1 - \sum_{i=1}^{m} \tilde{W}_{i}^{(t-1)} y_{i} h(x_{i}; \hat{\theta}_{t}) \right)
\]

2. Because \( \tilde{W}_{i}^{(t-1)} \geq 0 \) and \( \sum_{i=1}^{m} \tilde{W}_{i}^{(t-1)} = 1 \), it follows that \( \sum_{i=1}^{m} \tilde{W}_{i}^{(t-1)} y_{i} h(x_{i}; \theta) \in [-1, +1] \), therefore

\[
1 - (\sum_{i \in C} \tilde{W}_{i}^{(t-1)} - \sum_{i \in M} \tilde{W}_{i}^{(t-1)}) = 1 - \sum_{i=1}^{m} \tilde{W}_{i}^{(t-1)} y_{i} h(x_{i}; \hat{\theta}_{t}) \in [0, +2], \text{ and so}
\]

\[
\frac{1}{2} \left( 1 - \sum_{i=1}^{m} \tilde{W}_{i}^{(t-1)} y_{i} h(x_{i}; \hat{\theta}_{t}) \right) \in [0, +1].
\]
We are now ready to cast the steps of the boosting algorithm in a form similar to the AdaBoost algorithm given at CMU, 2015 fall, Z. Bar-Joseph, E. Xing, HW4, pr. 2.1-5. [Assume $\tilde{W}_i(0) = \frac{1}{m}$ and $f_0(x_i) = 0$ for $i = 1, \ldots, m$.]

**Step 1:** Find any classifier $h(x; \hat{\theta}_t)$ that performs better than chance with respect to the weighted training error:

$$\varepsilon_t = \frac{1}{2} \left( 1 - \sum_{i=1}^{m} \tilde{W}_i^{(t-1)} y_i h(x_i; \hat{\theta}_t) \right).$$  \hspace{1cm} (15)

**Step 2:** Set the votes $\alpha_t$ for the new component by minimizing the overall empirical loss:

$$J_t(\alpha, \hat{\theta}_t) = \frac{1}{m} \sum_{i=1}^{m} \text{Loss}(y_i f_{t-1}(x_i) + y_i \alpha h(x_i; \hat{\theta}_t)), \text{ and so } \alpha_t = \arg \min_{\alpha \geq 0} J_t(\alpha, \hat{\theta}_t).$$

**Step 3:** Recompute the normalized weights for the next iteration according to

$$\tilde{W}_i^{(t)} = -c_t \cdot dL\left(y_i f_{t-1}(x_i) + y_i \alpha_t h(x_i; \hat{\theta}_t) \right) \text{ for } i = 1, \ldots, m,$$  \hspace{1cm} (16)

where $c_t$ is chosen so that $\sum_{i=1}^{m} \tilde{W}_i^{(t)} = 1$. 
One more remark (by Liviu Ciortuz),
now concerning Step 1:

Normally there should be such \( \varepsilon_t \in (0, 1/2) \) (in fact, some corresponding \( \hat{\theta}_t \)), because if for some \( h \) we would have \( \varepsilon_t \in (1/2, 1) \), then we can take \( h' = -h \), and the resulting \( \varepsilon'_t \) would belong to \( (0, 1/2) \).

The are only two exceptions, which correspond to the case when for any hypothesis \( h \) we would have
- either \( \varepsilon_t = 1/2 \), in which case \( \sum_{i \in C} \tilde{W}_i^{(t-1)} = \sum_{i \in M} \tilde{W}_i^{(t-1)} \)
- or \( \varepsilon_t \in \{0, 1\} \), in which case either \( h \) or \( h' = -h \) is a perfect (therefore not weak) classifier for the given training data.

Iteration 3
a. Show that the three steps in the algorithm correspond exactly to AdaBoost when the loss function is the exponential loss $\text{Loss}(z) = \exp(-z)$.

More precisely, show that in this case the setting of $\alpha_t$ based on the new weak classifier and the weight update to get $\tilde{W}_i^{(t)}$ would be identical to AdaBoost. (In CMU, 2015 fall, Z. Bar-Joseph, E. Xing, HW4, pr. 2.1-5, $\tilde{W}_i^{(t)}$ corresponds to $D_{t+1}(i)$.)

Solution

For the first part, we will show that the minimization in Step 2 of the general algorithm (LHS below), with $\text{Loss}(z) = e^{-z}$, is the same as the minimization performed by AdaBoost (RHS below), i.e. that

$$\arg\min_{\alpha > 0} \sum_{i=1}^{m} \text{Loss}(y_i f_{t-1}(x_i) + \alpha y_i h(x_i; \hat{\theta}_t)) = \arg\min_{\alpha > 0} \sum_{i=1}^{m} \tilde{W}_i^{(t-1)} \exp(-\alpha y_i h(x_i; \hat{\theta}_t)),$$

with (from AdaBoost)

$$\tilde{W}_i^{(t-1)} = c_{t-1} \cdot \exp(-y_i f_{t-1}(x_i)),$$

where $c_{t-1}$ is a normalization constant (weights sum to 1).
Solution (cont’d)

Evaluating the objective in LHS gives:

\[
\sum_{i=1}^{m} \text{Loss}(y_i f_{t-1}(x_i) + \alpha y_i h(x_i; \hat{\theta}_t))
\]

\[= \sum_{i=1}^{m} \exp(-y_i f_{t-1}(x_i)) \exp(-\alpha y_i h(x_i; \hat{\theta}_t)) = \frac{1}{c_{t-1}} \sum_{i=1}^{m} \tilde{W}_i^{(t-1)} \exp(-\alpha y_i h(x_i; \hat{\theta}_t))
\]

\[= \frac{1}{c_{t-1}} \left[ \sum_{i \in \{i \mid y_i h(x_i; \hat{\theta}_t) = 1\}} \left( \tilde{W}_i^{(t-1)} \right) e^{-\alpha} + \sum_{i \in \{i \mid y_i h(x_i; \hat{\theta}_t) = -1\}} \left( \tilde{W}_i^{(t-1)} \right) e^{\alpha} \right],
\]

which is proportional to the objective minimized by AdaBoost (see CMU, 2008 fall, Eric Xing, HW3, pr. 4.1.1). Therefore, minimizing w.r.t the value of \( \alpha \) is the same for both algorithms.

For the second part, note that the weight assignment in Step 3 of the general algorithm (for stage \( t \)) is

\[
\tilde{W}_i^{(t)} = -c_t \cdot dL(y_i f_t(x_i)) = c_t \cdot \exp(-y_i f_t(x_i)),
\]

which is the same as in AdaBoost (see CMU, 2015 fall, Z. Bar-Joseph, E. Xing, HW4, pr. 2.2).
b. Show that for any valid loss function of the type discussed above, the new component \( h(x; \hat{\theta}_t) \) just added at the \( t \)-th iteration would have weighted training error exactly \( 1/2 \) relative to the updated weights \( \tilde{W}_i^{(t)} \).

**Solution**

At stage \( t \), \( \alpha_t \) is chosen to minimize \( J_t(\alpha, \hat{\theta}_t) \), i.e. to solve \( \frac{\partial J_t(\alpha, \hat{\theta}_t)}{\partial \alpha} = 0 \). In general,

\[
\frac{\partial}{\partial \alpha} J_t(\alpha, \hat{\theta}_t) = \frac{1}{m} \sum_{i=1}^{m} \frac{\partial}{\partial \alpha} \text{Loss}(y_i f_{t-1}(x_i) + y_i \alpha h(x_i; \hat{\theta}_t))
\]

\[
= \frac{1}{m} \sum_{i=1}^{m} dL(y_i f_{t-1}(x_i) + y_i \alpha h(x_i; \hat{\theta}_t)) y_i h(x_i; \hat{\theta}_t) \propto \sum_{i=1}^{m} \tilde{W}_i^{(t)} y_i h(x_i; \hat{\theta}_t),
\]

so that we must have \( \tilde{W}_i^{(t)} y_i h(x_i; \hat{\theta}_t) = 0 \). Then, the weighted training error for \( h(x; \hat{\theta}_t) \) (relative to the updated weights \( \tilde{W}_i^{(t)} \) determined by \( \alpha_t \)) can be computed in a similarly way to (15):

\[
\frac{1}{2} \left( 1 - \sum_{i=1}^{m} \tilde{W}_i^{(t)} y_i h(x_i; \hat{\theta}_t) \right) = \frac{1}{2} (1 - 0) = \frac{1}{2}.
\]
c. Now, suppose that we change the objective function to $J_t = \sum_{i=1}^{m} (y_i - f_t(x_i))^2$ and we still want to optimize it sequentially. What is the new update rule for $\alpha_t$?

Solution

We will compute the derivative of $J_t = \sum_{i=1}^{m} (y_i - f_t(x_i))^2$ w.r.t. $\alpha_t$ and set it to zero to find the value of $\alpha_t$.

$$\frac{\partial J_t}{\partial \alpha_t} = \frac{\partial \sum_{i=1}^{m} (y_i - f_t(x_i))^2}{\partial \alpha_t} = \sum_{i=1}^{m} 2(y_i - f_t(x_i)) \frac{\partial (y_i - f_t(x_i))}{\partial \alpha_t}.$$  

We also know that

$$f_t(x_i) = f_{t-1}(x_i) + \alpha_t h_t(x_i).$$

In this equation, $f_{t-1}$ is independent of $\alpha_t$. Substituting this in the derivative equation, we get

$$\frac{\partial J_t}{\partial \alpha_t} = 2 \sum_{i=1}^{m} (y_i - f_t(x_i)) \frac{\partial (y_i - f_{t-1}(x_i) - \alpha_t h_t(x_i))}{\partial \alpha_t} = 2 \sum_{i=1}^{m} (y_i - f_t(x_i)) (-h_t(x_i)).$$

\textsuperscript{a}LC: Note that $(y_i - f(x_i))^2 = (1 - y_i f_t(x_i))^2 = (1 - z_i)^2$, where $z_i = y_i f_t(x_i)$. The function $(1 - z)^2$ is derivable and convex; it is decreasing on $(-\infty, 1]$ and increasing on $[1, +\infty)$.  

Solution (cont’d)

Setting the derivative to zero, we get

\[
\frac{\partial J_t}{\partial \alpha_t} = 0 \iff \sum_{i=1}^{m} (y_i - f_t(x_i))h_t(x_i) = 0 \iff \sum_{i=1}^{m} (y_i - \alpha_t h_t(x_i) - f_{t-1}(x_i))h_t(x_i) = 0
\]

\[
\sum_{i=1}^{m} (y_i - f_{t-1}(x_i))h_t(x_i) = \alpha_t \sum_{i=1}^{m} h_t^2(x_i) \iff \alpha_t = \frac{\sum_{i=1}^{m} (y_i - f_{t-1}(x_i))h_t(x_i)}{\sum_{i=1}^{m} h_t^2(x_i)}
\]

\[
\iff \alpha_t = \frac{1}{m} \sum_{i=1}^{m} (y_i - f_{t-1}(x_i))h_t(x_i).
\]
d. Show that if we use the *logistic loss* instead [of the exponential loss] the unnormalized weights $W_i^{(t)}$ are bounded by 1.

**Solution**

$W_i^{(t)}$ was defined as $-dL(y_i f_t(x_i))$, with $dL(z) \not= \frac{\partial}{\partial z}(\ln(1 + e^{-z}))$. Therefore,

$$W_i^{(t)} = \frac{e^{-z_i}}{1 + e^{-z_i}} = \frac{1}{1 + e^{z_i}} < 1,$$

where $z_i = y_i f_t(x_i)$. 
e. When using the logistic loss, what are the normalized weights, $\tilde{W}_i^{(t)}$? Express the weights as a function of the agreements $y_if_t(x_i)$, where we have already included the $t$-th weak learner.

What can you say about the resulting normalized weights for examples that are clearly misclassified in comparison to those that are just slightly misclassified by the current ensemble?

If the training data contains mislabeled examples, why do we prefer the logistic loss over the exponential loss, $\text{Loss}(z) = \exp(-z)$?

**Solution**

The normalized weights are given by $\tilde{W}_i^{(t)} = c_t \cdot \frac{\exp(-y_if_t(x_i))}{1 + \exp(-y_if_t(x_i))}$, with the normalization constant $c_t = \left(\sum_{i=1}^{m} \frac{\exp(-y_if_t(x_i))}{1 + \exp(-y_if_t(x_i))}\right)^{-1}$.

[Answer from MIT, 2011 fall, Leslie P. Kaelbling, HW5, pr. 1.1]

For clearly misclassified examples, $y_if_t(x_i)$ is a large negative, so $W_i^{(t)}$ is close to [and less than] 1, while for slightly misclassified examples, $W_i^{(t)}$ is close to [and greater than] 1/2. Thus, the normalized weights for the two respective cases will be in a ratio of at most 2 : 1, i.e. a single clearly misclassified outlier will never be worth more than two completely uncertain points. This is why boosting with logistic loss function is robust to outliers.
Solution (cont’d) in Romanian

LC: Pentru ultima parte de la punctul e nu am găsit deloc răspuns la MIT, însă pot gândi astfel:

În cazul funcției de pierdere logistice, dacă avem un $x_i$ care ar avea de drept eticheta $y_i = +1$, dar se consideră (în mod eronat) $y_i = -1$, pierderea este de aproximativ $f_t(x_i)$ dacă $f_t(x_i) > 0$, în vreme ce în cazul funcției de pierdere [negativ] exponențiale pierderea este $\exp(f_t(x_i))$ care este în general mult mai mare decât $f_t(x_i)$. Cazurile simetrice ($f_t(x_i) \leq 0$ și apoi $y_i = -1 \rightarrow +1$) se tratează în mod similar.

\(^a\)Vedeți graficul funcției de pierdere logistică din enunțul problemei de față.
f. Suppose we use logistic loss. What is the update rule for $\alpha_t$?

**Solution (in Romanian);** initially written by Ștefan Matcovici (MSc student)

În loc să minimizăm $J_t$ în raport cu argumentul $\alpha$, vom încerca să minimizăm în raport cu $\alpha$ o *margine superioară* pentru diferența dintre $J_t$ și $J_{t-1}^*$, unde $J_{t-1}^* = \min_{h \in \mathcal{H}, \alpha \in \mathbb{R}^+} J_{t-1}(h, \alpha)$. (Spre deosebire de $J_t$ care depinde de $\alpha$, $J_{t-1}^*$ nu depinde de $\alpha$. Prin urmare, a minimiza $J_t$ în raport cu $\alpha$ este echivalent cu a minimiza $J_t - J_{t-1}^*$ în raport cu $\alpha$.)
\[ J_t - J_{t-1}^* = \sum_{i=1}^{m} \ln(1 + \exp(-y_i f_t(x_i))) - \sum_{i=1}^{m} \ln(1 + \exp(-y_i f_{t-1}(x_i))) = \sum_{i=1}^{m} \frac{1 + \exp(-y_i f_t(x_i))}{1 + \exp(-y_i f_{t-1}(x_i))} \]

\[ = \sum_{i=1}^{m} \ln \left( 1 + \frac{\exp(-y_i f_t(x_i)) - \exp(-y_i f_{t-1}(x_i))}{1 + \exp(-y_i f_{t-1}(x_i))} \right) \]

\[ = \sum_{i=1}^{m} \ln \left( 1 + \frac{\exp(-y_i f_{t-1}(x_i) - y_i \alpha h(x_i)) - \exp(-y_i f_{t-1}(x_i))}{1 + \exp(-y_i f_{t-1}(x_i))} \right) \]

\[ = \sum_{i=1}^{m} \ln \left( 1 + \frac{\exp(-y_i f_{t-1}(x_i)) [\exp(-y_i \alpha h(x_i)) - 1]}{1 + \exp(-y_i f_{t-1}(x_i))} \right) \]

\[ = \sum_{i=1}^{m} \ln \left( 1 + \frac{\exp(-y_i \alpha h(x_i)) - 1}{1 + \exp(-y_i f_{t-1}(x_i)) + 1} \right) = \sum_{i=1}^{m} \ln \left( 1 + \frac{\exp(-y_i \alpha h(x_i)) - 1}{\exp(y_i f_{t-1}(x_i)) + 1} \right) \]

\[ \leq \sum_{i=1}^{m} \frac{\exp(-y_i \alpha h(x_i)) - 1}{\exp(y_i f_{t-1}(x_i)) + 1} \]

\[ \text{fiindcă } \ln(1 + z) \leq z, \forall z > -1. \]
Remarcați faptul că logaritmul din expresia (17) există, întrucât

$$\frac{\exp(-y_i \alpha h(x_i)) - 1}{\exp(y_i f_{t-1}(x_i)) + 1} > -1 \iff \exp(-y_i \alpha h(x_i)) - 1 > -\exp(y_i f_{t-1}(x_i)) - 1$$

$$\iff \underbrace{\exp(-y_i \alpha h(x_i))}_{>0} > \underbrace{-\exp(y_i f_{t-1}(x_i))}_{<0},$$

înegalitate adevărată pentru $\forall \alpha$.

Expresia (18) pe care tocmai am obținut-o mai sus este *marginea superioară* (engl., upper bound) pentru $J_t - J_{t-1}$ pe care o vom minimiza în raport cu $\alpha$. 
Un calcul simplu ne arată că
\[
\frac{\partial}{\partial z} \ln(1 + e^{-z}) = \frac{-e^{-z}}{1 + e^{-z}} = -\frac{1}{e^{-z}} = -\frac{1}{e^z + 1}. \tag{19}
\]

Știm din enunț că \(W_{i}^{(t-1)} = -dL(y_i f_{i-1}(x_i))\). Conform relației (19), rezultă că
\[
W_{i}^{(t-1)} = -\left( -\frac{1}{\exp(y_i f_{i-1}(x_i)) + 1} \right) = \frac{1}{\exp(y_i f_{i-1}(x_i)) + 1},
\]

iar
\[
\tilde{W}_{i}^{(t-1)} = c_{t-1} \cdot \frac{1}{\exp(y_i f_{i-1}(x_i)) + 1},
\]
unde \(c_{t-1}\) este constanta de normalizare a ponderilor \(W_{i}^{(t-1)}\).
Prin urmare,

\[ J_t - J_{t-1} \leq \sum_{i=1}^{m} \frac{1}{\exp(y_i f_{t-1}(x_i)) + 1} (\exp(-y_i \alpha h(x_i)) - 1) \]

\[ = \frac{1}{c_{t-1}} \sum_{i=1}^{m} \tilde{W}_i^{(t-1)} \cdot (\exp(-y_i \alpha h(x_i)) - 1) \]

\[ \propto \sum_{i=1}^{m} \tilde{W}_i^{(t-1)} \cdot \exp(-y_i \alpha h(x_i)) - \sum_{i=1}^{m} \tilde{W}_i^{(t-1)}. \]

Așadar, a minimiza marginea superioară pentru \( J_t - J_{t-1} \) revine la a minimiza (în raport cu \( \alpha \)) expresia \( \sum_{i=1}^{m} \tilde{W}_i^{(t-1)} \cdot \exp(-y_i \alpha h(x_i)) \), pe care am întâlnit-o și la optimizarea costului [negativ] exponențial. Putem conchide că și în cazul funcției de cost logistice putem alege \( \alpha_t = \frac{1}{2} \ln \frac{1 - \varepsilon_t}{\varepsilon_t} \).
g. Suppose again that we use logistic loss and the training set is linearly separable. We would like to use a linear support vector machine (no slack penalties) as a base classifier [LC: or any linear separator consistent with the training data]. Assume that the generalized AdaBoost algorithm minimizes the $\varepsilon_t$ weighted error at Step 1. In the first boosting iteration, what would the resulting $\alpha_1$ be?
Solution

In Step 1, we pick $\theta_1$. We wish to find $\theta_1$ to minimize $\frac{\partial J_t(\alpha, \theta)}{\partial \alpha}|_{\alpha=0}$. Equivalently, this $\theta_1$ is chosen to minimize the weighted sum: $2\varepsilon_1 - 1 = -\sum_{i=1}^{m} \tilde{W}_0(i)y_i h(x_i; \theta)$, where $\tilde{W}_0(i) = \frac{1}{m}$ for all $i = 1, 2, \ldots, m$. If the training set is linearly separable with offset, then the no-slack SVM problem is feasible. Hence, the base classifier in this case will thus be an affine (linear with offset) separator $h(\cdot; \theta_1)$, which satisfies the inequality $y_i h(x_i; \theta_1) \geq 1$ for all $i = 1, 2, \ldots, m$.

In Step 2, we pick $\alpha_1$ to minimize $J_t(\alpha_1, \theta_1) = \frac{1}{m} \sum_{i=1}^{m} L(y_i h_0(x_i) + \alpha_1 y_i h(x_i; \theta_1)) = \frac{1}{m} \sum_{i=1}^{m} L(\alpha_1 y_i h(x_i; \theta_1))$. Note that $J_t(\alpha_1, \theta_1)$ is a sum of terms that are strictly decreasing in $\alpha_1$ (as $y_i h(x_i; \theta_1) \geq 1$); therefore, it itself is also strictly decreasing in $\alpha_1$. It follows that the boosting algorithm with logistic loss will take $\alpha_1 = \infty$ in order to minimize $J_t(\alpha_1, \theta_1)$.

This makes sense, because if we can find a base classifier that perfectly separates the data, we will weight it as much as we can to minimize the boosting loss. The lesson here is simple: when doing boosting, we need to use base classifiers that are not powerful enough to perfectly separate the data.
